4.5.36 Exercise 4.18 — checking the number domain

In Example 4.3 there are many unproved assertions about N and F. These should be checked. In particular, the isomorphism theorem of 4.6 could be proved by constructing a simple domain M from $\mathbf{M}$ in the way N is constructed from $\mathbf{N}$.

Classification of number-domain elements, injectivity of numerals and the successor map, and distinguished constants are with the Number-domain checks peer.

Theorem (`example_418`). Each element of the number domain is bottom or a numeral; numerals and successor action are injective; zero is not a successor numeral nor the successor image of a numeral.

Proof. Combine element classification with the numeral, successor, and constant distinction lemmas from the number-domain checks. ■

4.5.37 Peano structure on sequences

Head-test maps, unary numerals, and Peano axioms on the sequence domain.

Definition (`headValC`). Head-test evaluation on strings for cone versus singleton branches.

Proof. As in the formal module. ■ **Theorem (`headValC_nil`).** Head-test on the empty string returns the default.

Proof. As in the formal module. ■ **Theorem (`headValC_false`).** Head-test on a false prefix returns the first branch.

Proof. As in the formal module. ■ **Theorem (`headValC_true`).** Head-test on a true prefix returns the second branch.

Proof. As in the formal module. ■ **Definition (`T`).** The two-element token domain for sequence values.

Proof. As in the formal module. ■ **Theorem (`headValC_bot_le`).** Head-test on bottom prefixes is monotone in the prefix order.

Proof. As in the formal module. ■ **Theorem (`not_cone_subset_singleton`).** A cone neighbourhood is never contained in a singleton.

Proof. As in the formal module. ■ **Theorem (`cone_ne_singleton`).** Cone and singleton neighbourhoods are distinct.

Proof. As in the formal module. ■ **Definition (`liftC`).** Universal approximable map from the sequence domain using head-test values.

Proof. As in the formal module. ■ **Definition (`emptyMap`).** Constant false head-tests with bottom on cones.

Proof. As in the formal module. ■ **Theorem (`liftC_strBot`).** The lift sends stratum bottoms to cone values.

Proof. As in the formal module. ■ **Theorem (`liftC_strElem`).** The lift sends stratum elements to singleton values.

Proof. As in the formal module. ■ **Theorem (`emptyMap_strElem`).** Empty map values on stratum elements.

Proof. As in the formal module. ■ **Theorem (`emptyMap_strBot`).** Empty map values on stratum bottoms.

Proof. As in the formal module. ■ **Definition (`oneMap`).** Map sending cones to bottom/false/true pattern.

Proof. As in the formal module. ■ **Definition (`zeroMap`).** Map with true on singleton tails and mixed cones.

Proof. As in the formal module. ■ **Theorem (`zeroMap_strElem`).** Zero map on stratum elements.

Proof. As in the formal module. ■ **Theorem (`zeroMap_strBot`).** Zero map on stratum bottoms.

Proof. As in the formal module. ■ **Theorem (`oneMap_strElem`).** One map on stratum elements.

Proof. As in the formal module. ■ **Theorem (`oneMap_strBot`).** One map on stratum bottoms.

Proof. As in the formal module. ■ **Definition (`oneDef`).** Fixed-point-style definition of the numeral one map.

Proof. As in the formal module. ■ **Theorem (`condT_bot`).** Conditional with bottom first argument is bottom.

Proof. As in the formal module. ■ **Theorem (`one_def_strBot`).** The simple one map agrees with the fixed-point definition on stratum bottoms.

Proof. As in the formal module. ■ **Theorem (`one_def_strElem`).** The simple one map agrees with the fixed-point definition on stratum elements.

Proof. As in the formal module. ■ **Theorem (`peano_cons_disjoint`).** Prefixes false and true yield distinct strings.

Proof. As in the formal module. ■ **Theorem (`peano_cons_injective`).** Equality of conses implies equality of tails.

Proof. As in the formal module. ■ **Theorem (`peano_induction`).** Induction on finite bit-strings.

Proof. As in the formal module. ■ **Theorem (`peano_nil_ne_cons`).** The empty string is not a cons.

Proof. As in the formal module. ■

4.5.38 Exercise 4.19 — Peano axioms for sequences

There are many unproved assertions in Example 4.4! In particular discuss "Peano's Axioms" for $\{0,1\}^*$. Show, moreover, that $\mathrm{one} : C \to T$ can be defined from the rest of the structure by a fixed-point equation.

The development is with the Peano structure on sequences peer.

Theorem (`example_419`). Finite bit-strings satisfy Peano's axioms; the explicit one-map agrees with the fixed-point definition of the numeral one on each stratum.

Proof. Combine the Peano lemmas and the stratum comparison theorems from the sequence Peano peer. ■

4.5.39 Fix of a composite

For approximable endomaps f and g, the least fixed point of $f \circ g$ maps to that of $g \circ f$ under f, and conversely by symmetry.

Theorem (`comp_fixElement_isFixed`). The composite $f \circ g$ fixes the image under f of the least fixed point of $g \circ f$.

Proof. Apply the composition law for elementwise images and the fixed-point law for the least fixed point of $g \circ f$. ■

Theorem (`fixElement_comp_comm`). The least fixed points of $f \circ g$ and $g \circ f$ are related by f on the elementwise order.

Proof. Use leastness and the preceding fixed-point transfer, then symmetry with roles reversed. ■

4.5.40 Exercise 4.20 — fix of a composite

For approximable $f, g : D \to D$ prove that

$$\mathrm{fix}(f \circ g) = f(\mathrm{fix}(g \circ f)).$$

The development is with the Fix of a composite peer.

Theorem (`example_420`). For approximable f, g,
$mathrmfix(f$
$circg) = f($
$mathrmfix(g$
$circf))$.

Proof. Apply the composite fixed-point commutation law. ■

4.5.41 Order as a fixed point

Order, successor towers, and multiplication as powerset least fixed points.

Definition (`leOp`). The order operator unions the diagonal with one-step successor pairs from a relation.

Proof. As in the formal module. ■ **Definition (`leRel`).** The standard less-than-or-equal relation on $\mathbb{N} \times \mathbb{N}$.

Proof. As in the formal module. ■ **Definition (`mulOp`).** For fixed n, multiply a set by adjoining 0 and all $n + m$ with m in the set.

Proof. As in the formal module. ■ **Definition (`succImage`).** Successor image $x^+ = \{k \mid \exists j \in x,\ k = j + 1\}$.

Proof. As in the formal module. ■ **Definition (`upSet`).** The upward-closed set $\{k \mid m \leq k\}$.

Proof. As in the formal module. ■ **Definition (`addIso`).** Isomorphism between $\mathbb{N}$ and integers at least m.

Proof. As in the formal module. ■ **Theorem (`addIso_apply`).** The addition isomorphism sends n to $m + n$.

Proof. As in the formal module. ■ **Theorem (`addIso_succ`).** The addition isomorphism commutes with successor.

Proof. As in the formal module. ■ **Theorem (`addIso_zero`).** The addition isomorphism sends 0 to m.

Proof. As in the formal module. ■ **Theorem (`leOp_monotone`).** The order operator is monotone on subsets of pairs.

Proof. As in the formal module. ■ **Theorem (`leRel_isFixed`).** The standard order is a fixed point of the order operator.

Proof. As in the formal module. ■ **Theorem (`mem_fixedPoint_iff`).** Membership in a fixed order relation is equivalent to $n \leq m$.

Proof. As in the formal module. ■ **Theorem (`leOp_unique`).** Every fixed point of the order operator equals the standard order.

Proof. As in the formal module. ■ **Theorem (`mulOp_monotone`).** The multiplication operator is monotone.

Proof. As in the formal module. ■ **Theorem (`mulOp_lfp_eq_multiples`).** The least fixed set for n is the set of multiples of n.

Proof. As in the formal module. ■ **Theorem (`upSet_succ`).** Successor shift of an upward set is the successor image.

Proof. As in the formal module. ■ **Theorem (`upSet_zero`).** The upward set from 0 is the universe.

Proof. As in the formal module. ■ **Theorem (`upSet_unique`).** The upward-set tower is uniquely determined by zero and successor image.

Proof. As in the formal module. ■

4.5.42 Exercise 4.21 — order as a fixed point

Show that the less-than-or-equal-to relation $\ell \subseteq \mathbf{N} \times \mathbf{N}$ is uniquely determined by the fixed point equation

$$\ell = \{(n, n) \mid n \in \mathbf{N}\} \cup \{(n, m^+) \mid (n, m) \in \ell\}.$$

Consider the structured set $\langle P\mathbf{N}, \mathbf{N}, {}^+\rangle$ where, as before, $x^+ = \{n^+ \mid n \in x\}$.

What is the unique function $[\cdot] : \mathbf{N} \to P\mathbf{N}$ given by 4.13(3)? Prove that the structures $\langle \mathbf{N}, 0, {}^+\rangle$ and $\langle [m], m, {}^+\rangle$ are uniquely isomorphic for each $m \in \mathbf{N}$, and connect the isomorphism with ordinary addition of integers. Can the same be done for multiplication? (Hint: Consider the fixed-point equation

$$n \cdot \mathbf{N} = \{0\} \cup \{n + m \mid m \in n \cdot \mathbf{N}\},$$

where $n \in \mathbf{N}$ is fixed.)

The development is with the Order as a fixed point peer.

Theorem (`example_421`). The standard order on
$mathbbN$
$times$
$mathbbN$ is the unique fixed point of the order operator; successor towers on

$mathbbN$ are uniquely determined; and for each n the least solution of the multiplication equation is the set of multiples of n.

Proof. Apply the uniqueness, fixed-point, and least-fixed-point lemmas of the order peer. ■

4.5.45 Unique fixed point

Under Eilenberg's hypotheses on approximating maps below the identity, an approximable endomap has exactly one fixed point, namely its least fixed point.

Theorem (`f_unique_fixedPoint`). If approximable maps a_n rise from bottom to the identity and commute with f on the stated scheme, there is a unique element x with $f(x) = x$.

Proof. Show every fixed x lies below and above the least fixed point of f by induction on stages using the LUB hypothesis and the commutation law. ■

4.5.46 Exercise 4.23 — commuting with the iterates

(Suggested by S. Eilenberg). Suppose $f : \mathcal{D} \to \mathcal{D}$ is approximable on a given domain $\mathcal{D}$. Suppose $a_n : \mathcal{D} \to \mathcal{D}$ is a sequence of approximable maps where

(i) $a_0(x) = \bot$, for all $x \in |\mathcal{D}|$;

(ii) $a_n \sqsubseteq a_{n+1}$ in $\mathcal{D} \to \mathcal{D}$, for all $n \in \mathbf{N}$;

(iii) $\bigsqcup_{n=0}^{\infty} a_n = I_{\mathcal{D}}$ in $\mathcal{D} \to \mathcal{D}$;

(iv) $a_{n+1} \circ f = a_{n+1} \circ f \circ a_n$, for all $n \in \mathbf{N}$.

Prove that f has a unique fixed point. (Hint: Show that if $x = f(x)$, then $a_n(x) \sqsubseteq a_n(\mathrm{fix}(f))$ for all $n \in \mathbf{N}$ by induction on n.)

The development is with the Unique fixed point peer.

Theorem (`example_423`). Unique fixed point under Eilenberg iterate hypotheses.

Proof. Invoke the peer library facts cited in the packaging theorem. ■

4.5.48 Exercise 4.24 — Schroeder-Bernstein theorem

(For set theorists). Let $f : A \to B$ and $g : B \to A$ be one-one functions (into, not necessarily onto!) Prove the Schroeder - Bernstein theorem to the effect that there exists a one-one correspondence $h : A \leftrightarrow B$. (Hint: (Suggested by A. Tarski). By the fixed-point theorem find $X \subseteq A$ where

$$X = (A - g(B)) \cup g(f(X)),$$

where $f(X) =$ the image of the set X under the function f. Define $h \subseteq A \times B$ as a union of two restrictions:

$$h = f \restriction X \cup g^{-1} \restriction (A - X).$$

A picture helps.)

The development is with the Schroeder-Bernstein peer.

Theorem (`example_424`). Schroeder–Bernstein from a Tarski-style least fixed set.

Proof. Invoke the peer library facts cited in the packaging theorem. ■

4.5.49 Unary sequence domain

Unary neighbourhood system, cons map, and comparison with the number domain.

Definition (`shift`). Successor neighbourhood shift on subsets of $\mathbb{N}$.

Proof. As in the formal module. ■ **Definition (`tail`).** Tail neighbourhood $\{m \mid n \leq m\}$.

Proof. As in the formal module. ■ **Theorem (`mem_tail`).** Characterisation of tail membership.

Proof. As in the formal module. ■ **Definition (`memC1`).** Neighbourhoods are tails or singletons.

Proof. As in the formal module. ■ **Theorem (`memC1_singleton`).** Singletons are valid neighbourhoods.

Proof. As in the formal module. ■ **Theorem (`memC1_tail`).** Tails are valid neighbourhoods.

Proof. As in the formal module. ■ **Theorem (`shift_mono`).** Shift is monotone in neighbourhood inclusion.

Proof. As in the formal module. ■ **Theorem (`shift_singleton`).** Shift sends $\{n\}$ to $\{n+1\}$.

Proof. As in the formal module. ■ **Theorem (`shift_tail`).** Shift sends tail n to tail $n+1$.

Proof. As in the formal module. ■ **Theorem (`memC1_shift`).** Shift preserves the unary neighbourhood class.

Proof. As in the formal module. ■ **Theorem (`singleton_tail_nd`).** Singleton and tail are nested, reversed, or disjoint.

Proof. As in the formal module. ■ **Theorem (`nestedOrDisjoint`).** Unary neighbourhoods form a nested-or-disjoint family.

Proof. As in the formal module. ■ **Theorem (`tail_zero`).** Tail from zero is the universe.

Proof. As in the formal module. ■ **Theorem (`memC1_univ`).** The universe is a unary neighbourhood.

Proof. As in the formal module. ■ **Definition (`C1`).** Unary sequence neighbourhood system on $\mathbb{N}$.

Proof. As in the formal module. ■ **Theorem (`C1_mem`).** Membership characterisation for unary neighbourhoods.

Proof. As in the formal module. ■ **Theorem (`C1_master`).** Master neighbourhood is the universe.

Proof. As in the formal module. ■ **Definition (`consMap`).** Approximable shift-by-successor on unary neighbourhoods.

Proof. As in the formal module. ■ **Definition (`infElt`).** Least fixed point of the cons map.

Proof. As in the formal module. ■ **Definition (`oneBot`).** Principal element for a tail neighbourhood.

Proof. As in the formal module. ■ **Definition (`oneElem`).** Principal element for a singleton neighbourhood.

Proof. As in the formal module. ■ **Definition (`relateNToC1`).** Constant numeral lift from the number domain.

Proof. As in the formal module. ■ **Theorem (`consMap_oneBot`).** Cons map increments the tail index.

Proof. As in the formal module. ■ **Theorem (`consMap_oneElem`).** Cons map increments the singleton index.

Proof. As in the formal module. ■ **Theorem (`infElt_eq`).** The infinite element is fixed by the cons map.

Proof. As in the formal module. ■ **Theorem (`relateNToC1_bot`).** The lift sends bottom to bottom.

Proof. As in the formal module. ■ **Theorem (`relateNToC1_natElem`).** The lift sends numerals to singleton principals.

Proof. As in the formal module. ■

4.5.50 Exercise 4.25 — unary sequence domain

Perhaps the domains $\mathbf{N}$ and C are not exactly analogous? C was based on $\{0,1\}$ as the underlying set of tokens. Construct a system C_1 based on $\{1\}^*$ (= finite strings of 1's) with neighbourhoods:

$$C_1 = \{\, \{1^m \mid m > n\} \mid n \in \mathbf{N} \,\} \cup \{\, \{1^n\} \mid n \in \mathbf{N} \,\}.$$

What structure should be put on C_1 strictly analogous to that on $C (= C_2)$? What kinds of approximable maps relate $\mathbf{N}$, C_1, and C_2? Draw some pictures.

The development is with the Unary sequence domain peer.

Theorem (`example_425`). Unary neighbourhood system, cons map, and comparison with the number domain.

Proof. Invoke the peer library facts cited in the packaging theorem. ■

4.6 Typed λ-calculus

<!DOCTYPE svg PUBLIC “-//W3C//DTD SVG 1.1//EN” “http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd”>

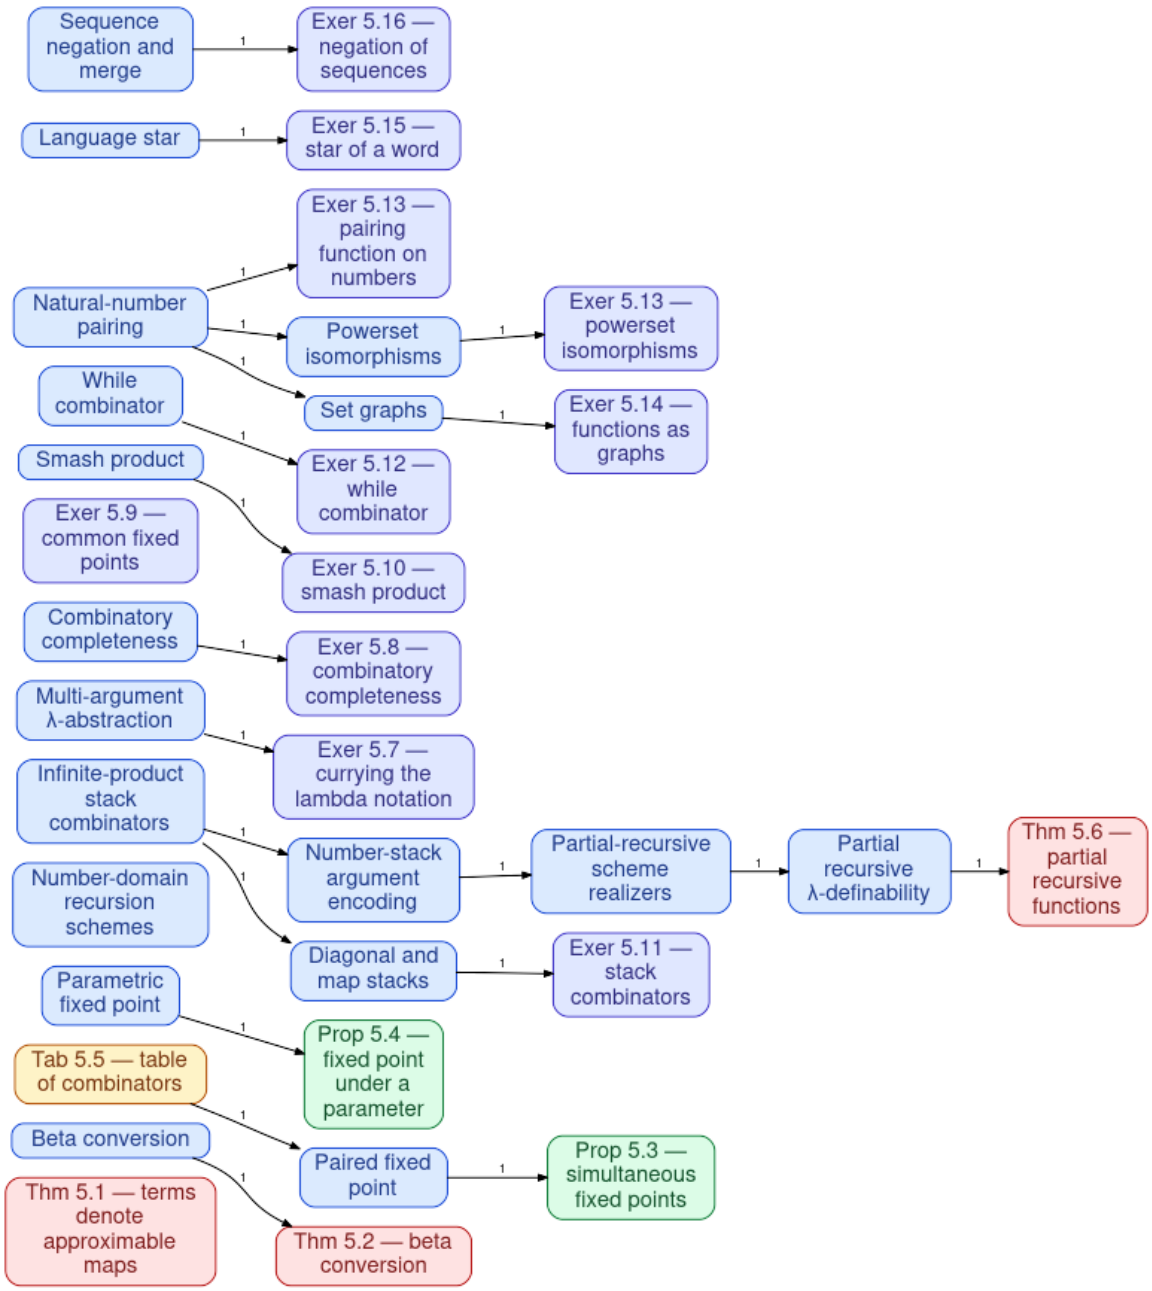

Figure 50: Diagram 15

4.6.1 Introduction

In Examples 4.3 and 4.4, after suitable domains have been constructed, functions are characterized by recursion equations whose form of expression is — basically — a composition or substitution of known functions

together with the function to be defined. This method can be made more precise and more easily usable by expanding our notation for functions — particularly by inventing a "temporary" notation for a function as a thing in itself without having to have special letters for functions. The device is called λ-*abstraction*. It is related to ordinary set abstraction (the $\{x \mid \ldots\}$ — notation already much used in these lectures), but we gear the approach to domains and their elements, and especially to function spaces.

At this stage it would not be so helpful to produce a rigorously formal definition of the syntax of the typed λ-calculus; we shall try to suggest what is needed by example. There are so many examples at hand, the less formal discussion ought to be sufficient.

In the first place we should set aside, in the notational store room as it were, a stock of variables

$$x, y, z, w, \ldots$$

These variables will be required in different "sizes" or "types". Roughly speaking there should be an infinite number of variables to range over the elements of each domain $\mathcal{D}$. We could perhaps write

$$x_0^{\mathcal{D}}, x_1^{\mathcal{D}}, x_2^{\mathcal{D}}, \ldots,$$

but the subscripts to insure an infinity of variables and the superscripts to record the typing of the variables lead to a notation as

tiresome to write as it is to read. We simply agree that we can have as many variables as we need and that they come in all the types.

Strictly speaking we should also introduce *type symbols* and not confuse types with domains. But if the reader will simply keep in mind that *form* in language has always to be kept distinct from *content*, the confusion at the type level will not matter so very much. A point at which the confusion might cause a real confusion concerns *compound types*. Given $\mathcal{D}_0$ and $\mathcal{D}_1$ we can form such compounds as

$$\mathcal{D}_0 + \mathcal{D}_1, \quad \mathcal{D}_0 \times \mathcal{D}_1, \quad \mathcal{D}_0 \to \mathcal{D}_1$$

What has to be remembered is that a compound domain (neighbourhood system), $\mathcal{D}_0 \times \mathcal{D}_1$ say, does not uniquely determine the "parts" $\mathcal{D}_0$ and $\mathcal{D}_1$. (We could make it do so, but it would cost some effort.) Of course, the symbol "$\mathcal{D}_0 \times \mathcal{D}_1$" has well defined parts. The point is that *different* ways of forming a compound domain could lead to the *same* result, meaning that a domain does not let us retrace its exact history of construction. Compound symbols, however, always carry their histories around with them, since otherwise they would not be readable. What we want, of course, are *both* domain symbols *and* domains, the latter being the *meanings* of the former. Most of the time we can happily pretend that it is only the domains themselves we have to think about.

Besides variables, we will also need certain *constants*. For instance, the symbol 0 (perhaps, better $0^{\mathbf{N}}$) denotes a certain element of $|\mathbf{N}|$. Similarly, in view of Theorem 4.2, for each domain $\mathcal{D}$ there is a well-determined element $\mathrm{fix}^{\mathcal{D}}$ of the compound type $((\mathcal{D} \to \mathcal{D}) \to \mathcal{D})$ denoting the least fixed-point operator. We have considered any number of similar constants of a great variety of types already (cf. 4.3 and 4.4; cond is an especially good one). We can say that the variables and constants are *atomic terms*, where "atomic" here means non-compound.

To form compound terms, there are several means: for example, if $\tau, \ldots, \sigma$ is a list of already obtained terms (including variables or constants), then we can form an ordered *tuple*

We have already done so in 3.1. If the types of $\tau, \ldots, \sigma$ are $D, \ldots, D'$, respectively, then the type of the tuple is the product domain

$$D \times \cdots \times D',$$

because we intend that the tuple denote an element of this domain. (The tuple notation for *functions* as in 3.3 is being forgotten for the time being.)

Next suppose that τ has type $(D_0 \to D_1)$ and σ has type D_0, then the usual *function-value* notation

$$\tau(\sigma)$$

is a compound term of type D_1. We also use

$$\tau(\sigma_0, \ldots, \sigma_{n-1})$$

as an abbreviation of

$$\tau(\langle \sigma_0, \ldots, \sigma_{n-1} \rangle),$$

where, if the types of $\sigma_0, \ldots, \sigma_{n-1}$ are $D_0, \ldots, D_{n-1}$, then the type of τ has to be of the form

$$((D_0 \times \cdots \times D_{n-1}) \to D_n)$$

where D_n is the type of the compound. In this manner, with functions applied to tuples, we have the full facility of substitution into functions of many variables just by iterating the notation.

Having taken into account *function value*, it remains to provide for *function definition*. Suppose that $x_0, \ldots, x_{n-1}$ is a list of distinct variables of types $D_0, \ldots, D_{n-1}$. Suppose further that τ is a term — no matter how complicated — of type D_n. Then we can regard τ as defining a function of n-variables of type

$$((D_0 \times \cdots \times D_{n-1}) \to D_n).$$

What we have not done is to reward our regard by, as yet, providing a quick-to-write "name" for that function. This we now do; it is called

$$\lambda x_0, \ldots, x_{n-1} \cdot \tau,$$

where we stress that the x_i must be *distinct* variables and that this
expression denotes the *whole function*. That is why we provide it with a special symbol.
Here is an example of the λ - notation

$$\lambda x, y.x,$$

which is read "lambda ex wye ... (pause) ... ex". If the types of x and y are D_0 and D_1, then the type of the above is

$$((D_0 \times D_1) \to D_0).$$

Indeed, we know this function very well: it is the *first projection function* p_0 of 3.3 and the equation

$$p_0 = \lambda x, y.x$$

is true, as is the equation

$$p_1 = \lambda x, y.y.$$

In the notation of 3.3, we also find the true equation

$$\langle f, g\rangle = \lambda w.\langle f(w), g(w)\rangle,$$

where on the right-hand side we are using "official" λ - notation for a function of type

$$(D_2 \to (D_0 \times D_1)).$$

The notation on the left is just an *abbreviation* and it should not be confused with the pair (2-tuple) of type

$$((D_2 \to D_0) \times (D_2 \to D_1)).$$

(Since the two domains just mentioned are *isomorphic*, the possible confusion is not all that serious. On the other hand, one confusion we will completely overlook is that between 1-tuples $\langle x\rangle$ and elements x. Strictly speaking they are different, but we shall not bother to make the distinction.)

Here are some other examples of true equations:

$$\mathrm{eval} = \lambda f, x.f(x) \qquad \text{(cf. 3.11)}$$

$$\mathrm{curry} = \lambda g\lambda x\lambda y.g(x, y) \qquad \text{(cf. 3.12)}$$

The first should be immediately clear; while the second is particularly *instructive*. What is being illustrated is that the λ - notation can

be *iterated*. The distinction being drawn is between

$$\lambda x_0, x_1, \ldots, x_{n-1}.\tau \quad \text{and} \quad \lambda x_0\lambda x_1 \ldots \lambda x_{n-1}.\tau.$$

The first has type

$$((D_0 \times D_1 \times \cdots \times D_{n-1}) \to D_n);$$

while the second has type

$$(D_0 \to (D_1 \to (\ldots (D_{n-1} \to D_n) \ldots))).$$

This is related also to the true equation

$$\mathrm{curry}(\lambda x, y.\tau) = \lambda x\lambda y.\tau,$$

which shows that there are operators relating to the two notations. The first is the *multivariate* form; the second is the *curried* form.

Here is another true equation

$$\mathrm{fix} = \mathrm{fix}(\lambda F\lambda f.f(F(f))),$$

where the fix on the left has type $((D \to D) \to D)$ and that on the right type

$$((((D \to D) \to D) \to ((D \to D) \to D)) \to ((D \to D) \to D)).$$

This is the content of Exercise 4.9. (This also shows why type superscripts are tiresome.)
The combination

$$\mathrm{fix}(\lambda x.\tau)$$

occurs so often, that from time to time we abbreviate it as

$$!x.\tau,$$

but remember it only makes sense if x and τ have the *same* type. For example in 4.3 we could have written

$$\sigma = !f\lambda n.\mathrm{cond}(\mathrm{zero}(n), 0, f(\mathrm{pred}(n)) + \mathrm{pred}(n))$$

and read this as

"σ is the least (recursively defined) function f whose value at n is cond $(\dots)$."

We note that in the so-called "body" of the expression inside the
cond-part the variable f occurs again. That is just the point! This is a *recursive definition*; it is made into an *explicit* definition by invoking the least fixed-point operator.

In a λ-expression, $\lambda x, y, z.\tau$, say, the variables x, y, z are being *bound* in τ; but τ may have other variables that are nowhere bound in τ and these remain *free variables* of the whole expression. Bound variables are *dummy variables* and may be rewritten by other variables; thus

$$\lambda x.\tau = \lambda y.\tau[y/x]$$

is a true equation *PROVIDED* the variable y does not occur in τ. In the equation the notation $\tau[y/x]$ means the result of *substituting* (*rewriting*) the variable y for the variable x throughout the term τ. We can also write $\tau[\sigma/x]$ for substituting a whole term σ for a variable in the other term.

We have already spoken of "true equations", but how do we know that these curious equations are meaningful at all? They are, but this is something that has to be proved.

4.6.2 Theorem 5.1 — terms denote approximable maps

THEOREM 5.1. Every typed λ-term τ defines an approximable function of its free variables.

Proof: We argue by an induction on the complexity of τ; there will only be a few cases to consider since the "syntax" of λ-terms is limited — even though terms can be of any length.

If τ is a variable or a constant there is nothing to prove. We already know that

$$x \mapsto x \qquad \text{and} \qquad x \mapsto k$$

are approximable functions.

Suppose τ has the form

$$\langle \sigma_0, \dots, \sigma_{n-1} \rangle.$$

Then the σ_i are less complex terms, and so we can assume — as our induction hypothesis — that they define approximable functions of the free variables. Having said this, we just apply the already

proved 3.4 to conclude (after a suitable generalization to the multivariate case) that τ, which takes on tuples as values, also defines an approximable function.

Next, suppose τ has the form

$$\sigma_0(\sigma_1),$$

where we are sure that the types of all the terms match properly. Again we can assume the σ_i to be well behaved. But the values we seek can also be written as

$$\mathrm{eval}(\sigma_0, \sigma_1).$$

Since eval is approximable by 3.11, we just have to invoke an instance of 3.7 to gain the desired conclusion.

Finally, suppose that τ has the form

$$\lambda x.\sigma.$$

By a judicious choice of the order of the variables in σ (including x), we can assume that σ defines an approximable function

$$g : D_0 \times \cdots \times D_{n-1} \times D_n \to D'$$

where D' is the type of σ, D_n is the type of x, and $D_0, \ldots, D_{n-1}$ are the types of the remaining free variables of σ. We apply 3.12 and obtain an approximable function

$$\mathrm{curry}(g) : D_0 \times \cdots \times D_{n-1} \to (D_n \to D').$$

But, this is just exactly the function defined by τ.

We leave as an exercise the more general case of a term τ of the form

$$\lambda x_0, \ldots, x_{k-1}.\sigma,$$

which has a string of bound variables. □

We can now say more precisely what it means to call $\sigma = \tau$ a "true equation". This means that, if we employ the method of the proof of 5.1, the two terms define the *same function* of the free variables. For example,

$$\lambda x.\tau = \lambda y.\tau[y/x]$$

is true, provided y does not occur free in the term τ, since the systematic generation of the function defined by $\lambda x.\tau$ does not depend on what the variable x *looks like* but only on its *position* in the term τ. Some other obviously desirable rules for generating true equations are stated in the exercises. But one rule is so basic that we state it here in full generality.

The curry, evaluation, constant, pairing, and projection elementwise laws used in the inductive cases are with the Domain constructs peers (notably Theorems 3.5 / 3.11–3.12, Proposition 3.4, and Lemma 3.6).

Theorem (`theorem_51`). The elementwise laws for currying, evaluation of a paired function-and-argument, constant maps, pairing, and the first projection of a pair hold for approximable maps.

Proof. Invoke the corresponding Domain-constructs lemmas for curry, evaluation of a paired pair, constants, pairing, and the first projection. ■

4.6.3 Beta conversion

Beta-conversion laws for approximable maps: evaluating a curried map at a constant argument, double currying, and currying a paired map.

Theorem (`evalMap_comp_paired_curry_const`). Evaluating the curry of a binary map paired with a constant argument equals substituting that constant into the uncurried map along the identity on the remaining argument.

Proof. Compare elementwise images, using the evaluation, curry, constant, pairing, and identity laws.

■

Theorem (`toElementMap_curry_curry`). A twice-curried map evaluates by nesting pairs of arguments.

Proof. Apply the curry evaluation law twice. ■

Theorem (`toElementMap_curry_paired`). The curry of a paired pair of maps evaluates to the pair of the curried evaluations.

Proof. Apply the curry and pairing evaluation laws. ■

4.6.4 Theorem 5.2 — beta conversion

THEOREM 5.2. For suitably typed λ-terms the following equation is true:

$$(\lambda x_0, \ldots, x_{n-1} \cdot \tau)(\sigma_0, \ldots, \sigma_{n-1}) = \tau[\sigma_0/x_0, \ldots, \sigma_{n-1}/x_{n-1}].$$

Proof: It will be sufficient to carry out the proof for $n = 1$. The proof proceeds by induction on the complexity of the term τ.

In case τ is a *constant* k, the result reads

$$(\lambda x.k)(\sigma) = k,$$

and this is a true equation.

In case τ is a *variable* (in particular, the variable x), the result reads

$$(\lambda x.x)(\sigma) = \sigma,$$

and again this is a true equation.

In case τ is a *tuple* (say, $\langle \tau_0, \tau_1 \rangle$) the result reads

$$(\lambda x.\langle \tau_0, \tau_1 \rangle)(\sigma) = \langle \tau_0[\sigma/x], \tau_1[\sigma/x] \rangle.$$

This is true, because the left-hand side can be transformed by the true equation

$$(\lambda x.\langle \tau_0, \tau_1 \rangle)(\sigma) = \langle (\lambda x.\tau_0)(\sigma), (\lambda x.\tau_1)(\sigma) \rangle;$$

and then we apply the inductive assumption for τ_0 and for τ_1.

In case τ is an *application*, we want (supposing the term is $\tau_0(\tau_1)$),

$$(\lambda x.\tau_0(\tau_1))(\sigma) = \tau_0[\sigma/x](\tau_1[\sigma/x]).$$

We can proceed as in the last case, noting that the left-hand side equals

$$\text{eval } ((\lambda x.\langle \tau_0, \tau_1 \rangle)\ (\sigma))\ .$$

In case τ is an *abstract* (say, $\lambda y.\tau_0$), we want

$$(\lambda x.\lambda y.\tau_0)\ (\sigma) = \lambda y.\tau_0[\sigma/x]$$

PROVIDED the variable y is not free in σ. For this we require the true equation

$$(\lambda x.\lambda y.\tau)\ (\sigma) = \lambda y.(\lambda x.\tau)\ (\sigma)\ .$$

We argue for this by letting g be the function of $n + 2$ free variables defined by τ. Then, by 5.1, the λ-term $\lambda x.\lambda y.\tau$ defines the function $\text{curry } (\text{curry } (g))$ of n arguments. We can call this function h for the moment. We can write

$$h(v)\ (\sigma)\ (y) = g(v, \sigma, y)\ ,$$

where v is a list of arguments. But, with an appropriate combinator inv, which applied to g inverts the order of the last two arguments, we can write

$$h(v)\ (\sigma)\ (y) = \mathrm{curry}\ (\mathrm{inv}\ (g))\ (v, y)\ (\sigma)\ .$$

But, $\mathrm{curry}\ (\mathrm{inv}\ (g))$ is just the function defined by $(\lambda x.\tau)$. So what we have proved as true is

$$(\lambda x.\lambda y.\tau)\ (\sigma)\ (y) = (\lambda x.\tau)\ (\sigma)\ .$$

But if y is not free in α and

$$\alpha(y) = \beta$$

is true, then so is

$$\alpha = \lambda y.\beta\ .$$

This completes the proof. □

We note that if τ' is the term $\lambda x, y.\tau$, then $\tau'(x, y)$ means the same as τ. This gives a convenient way of indicating free variables: we just write $\sigma(x, y)$ — where x, y are not free in σ — and this will have the same values as any term τ which does involve the extra free variables x and y. We use this notational device in the next theorem.

The beta-conversion laws for currying against a constant, double currying, and currying a paired map are with the beta conversion peer.

Theorem (`theorem_52`). Currying a map against a constant argument agrees with substitution into the uncurried map; a twice-curried map evaluates by nesting pairs; and the curry of a paired pair of maps evaluates componentwise.

Proof. Invoke the three beta-conversion laws. ■

4.6.5 Paired fixed point

Sectional least fixed points and the least fixed point of a paired pair of binary maps.

Definition (`ApproximableMap.secFixX`). The sectional least-fixed-point map of a binary endomap in the first argument composes the fix combinator with the curry of that map after swapping arguments.

Proof. By definition. ■

Definition (`ApproximableMap.outerOp`). The outer operator of a pair of binary maps composes the second with the pairing of the sectional least-fixed-point map and the identity.

Proof. By definition. ■

Definition (`ApproximableMap.sectionX`). The section of a binary map at a second-argument value is the recovered map after currying the swapped composite.

Proof. By definition. ■

Theorem (`ApproximableMap.outerOp_apply`). The outer operator evaluates by feeding the sectional least fixed point paired with the second argument into the second map.

Proof. Unfold the definition and apply the composition, pairing, and identity laws. ■

Theorem (`ApproximableMap.secFixX_apply`). The sectional least-fixed-point map evaluates to the least fixed-point element of the corresponding section.

Proof. Unfold the definitions and apply the composition and fix-combinator evaluation laws. ■

Theorem (`ApproximableMap.sectionX_apply`). A section evaluates by pairing the free argument with the fixed second argument into the original map.

Proof. Unfold the definition and apply the curry, composition, and swap laws. ■

Theorem (`ApproximableMap.secFixX_isFixed`). The sectional least fixed point is fixed by the original map when paired with the section parameter.

Proof. Rewrite via the sectional evaluation laws and apply the fixed-point law for least fixed-point elements. ■

Theorem (`ApproximableMap.fixElement_paired_eq`). The least fixed point of a paired pair of binary maps is the pair whose second coordinate is the least fixed point of the outer operator and whose first coordinate is the sectional least fixed point at that second coordinate.

Proof. Show the sectional pair is a fixed point of the paired map, then that it lies below the least fixed point by comparing sections and the outer operator against the least paired fixed point's components. ■

4.6.6 Proposition 5.3 — simultaneous fixed points

PROPOSITION 5.3. The least fixed point of $\lambda x, y.\ \langle \tau(x,y), \sigma(x,y)\rangle$ is the pair with coordinates
$!x.\ \tau(x,\ !y.\ \sigma(x,y))$ and
$!y.\ \sigma(!x.\ \tau(x,y), y)$.

Proof: (We are assuming that x and y are not free in τ and σ.) The purpose of the fixed-point search is to find the least solution of the pair of equations $x = \tau(x,y)$ and $y = \sigma(x,y)$. In other words, we are generalizing the fixed-point equation from one to two variables—and, of course, we could go much further to any number of variables. To this end, let
$y_* = !y.\ \sigma(!x.\ \tau(x,y), y)$, and
$x_* = !x.\ \tau(x, y_*)$.
Then
$x_* = \tau(x_*, y_*)$,
and
$y_* = \sigma(!x.\ \tau(x, y_*), y_*)$
$= \sigma(x_*, y_*)$.
This proves that $\langle x_*, y_*\rangle$ is one fixed-point pair.

Suppose, then, that $\langle x_0, y_0\rangle$ is the least solution. (Why does a least solution have to exist? Hint: Consider a suitable mapping of type $D_0 \times D_1 \to D_0 \times D_1$, where D_0 is the type of x and D_1 the type of y.) Then we know $x_0 = \tau(x_0, y_0)$ and $y_0 = \sigma(x_0, y_0)$, and also $x_0 \sqsubseteq x_*$ and $y_0 \sqsubseteq y_*$. But from
$\tau(x_0, y_0) \sqsubseteq x_0$,
it follows that
$!x.\ \tau(x, y_0) \sqsubseteq x_0$.
Consequently,

$$\sigma(!x.\tau(x, y_0), y_0) \sqsubseteq \sigma(x_0, y_0) \sqsubseteq y_0.$$

By the fixed-point definition of y_*, we have $y_* \sqsubseteq y_0$, so $y_* = y_0$; whence,

$$x_* = !x.\tau(x, y_*) = !x.\tau(x, y_0) \sqsubseteq x_0.$$

So also $x_* = x_0$. □ We have the right formula for y_0, and a similar argument gives x_0.

The purpose of giving the above proof was to illustrate the use of the least fixed-point operator in proofs. We have such true principles as:

$$!x.\tau(x) = \tau(!x.\tau(x));$$

and

$$\tau(y) \sqsubseteq y \text{ implies } !x.\tau(x) \sqsubseteq y,$$

provided, of course, that x is not free in τ. These, together with the monotonicity of all the functions, were just the methods used in the above proof. Here is another example.

The sectional least-fixed-point / outer-operator characterisation of the least paired fixed point is with the paired fixed point peer.

Theorem (`proposition_53`). The least fixed point of a paired pair of binary maps is the sectional pair built from the outer operator's least fixed point.

Proof. Invoke the paired least-fixed-point law. ■

Proposition_5_3.lean

4.6.7 Parametric fixed point

Parametric least fixed points and the recursion operator on the function space.

Definition (`ApproximableMap.pfix`). The parametric least-fixed-point map composes the fix combinator with the curry of a binary endomap.

Proof. By definition. ■

Definition (`ApproximableMap.recOp`). The recursion operator curries the composite of a binary endomap with the pairing of the second projection and evaluation.

Proof. By definition. ■

Definition (`ApproximableMap.section2`). The section of a binary endomap at a first-argument value is the recovered map after currying.

Proof. By definition. ■

Theorem (`ApproximableMap.pfix_apply`). The parametric least-fixed-point map evaluates to the least fixed-point element of the corresponding section.

Proof. Unfold the definitions and apply the composition and fix-combinator evaluation laws. ■

Theorem (`ApproximableMap.recOp_apply`). The recursion operator evaluates by pairing an argument with the recovered function's value at that argument.

Proof. Unfold curry and apply the composition, pairing, projection, and evaluation laws. ■

Theorem (`ApproximableMap.section2_apply`). A section evaluates by pairing the fixed first argument with the free second argument into the original map.

Proof. Unfold the definition and apply the curry evaluation law. ■

Theorem (`ApproximableMap.pfix_isFixed`). The parametric least fixed point is fixed by the original map when paired with the section parameter.

Proof. Rewrite via the sectional evaluation laws and apply the fixed-point law for least fixed-point elements. ■

Theorem (`ApproximableMap.pfix_eq_fixElement_recOp`). The parametric least-fixed-point map equals the map recovered from the least fixed-point element of the recursion operator.

Proof. Show the recursion-operator fix yields a postfixed point for each section, hence lies above the parametric fix; conversely, the filter of the parametric fix is a postfixed point of the recursion operator, so the recursion-operator fix lies below it after transport through the function-space equivalence. ■

4.6.8 Proposition 5.4 — fixed point under a parameter

PROPOSITION 5.4. Let x, y, and $\tau(x, y)$ be of the same type D and let g be of type $(D \to D)$, then the equation

$$\lambda x.!y.\tau(x, y) =!g.\lambda x.\tau(x, g(x))$$

is true.

Proof : Let f be the function on the left-hand side. We can write

$$f(x) =!y.\tau(x, y) = \tau(x, f(x)).$$

Therefore

$$f = \lambda x.\tau(x, f(x)),$$

and it follows that

$$g_0 =!g.\lambda x.\tau(x, g(x)) \sqsubseteq f.$$

Then we have at once, by definition of g_0,

$$g_0(x) = \tau(x, g_0(x)),$$

for any given x. But by definition of f we find

$$f(x) =!y.\tau(x, y) \sqsubseteq g_0(x).$$

As this holds for all x, then $f \sqsubseteq g_0$ follows. So the equation is true. □

The last proof is instructive as it uses equations and inclusions between functions. In particular we have just made use of the principle:

> if $\tau \sqsubseteq \sigma$ holds for all values of x,
> then $\lambda x.\tau \sqsubseteq \lambda x.\sigma$ holds.

This is another form of Theorem 3.13(i).

The parametric least-fixed-point / recursion-operator characterisation is with the parametric fixed point peer.

Theorem (`proposition_54`). The parametric least-fixed-point map equals the map recovered from the least fixed-point element of the recursion operator.

Proof. Invoke the parametric least-fixed-point law. ■

4.6.9 Table 5.5 — table of combinators

TABLE 5.5. In the displayed table we give a summary of uses of the λ-notation to define various combinators. We have mentioned some of these equations before, and there are some combinators here we have not mentioned before — their meanings, however, should be clear.

$$
\begin{aligned}
P_0 &= \lambda x, y.x \\
P_1 &= \lambda x, y.y \\
\text{pair} &= \lambda x \lambda y.\langle x, y\rangle \\
\text{n-tuple} &= \lambda x_0 \lambda x_1 \ldots \lambda x_{n-1}.\langle x_0, x_1, \ldots, x_{n-1}\rangle \\
\text{diag} &= \lambda x.\langle x, x\rangle \\
\text{funpair} &= \lambda f \lambda g \lambda x.\langle f(x), g(x)\rangle \\
\text{proj}_i^n &= \lambda x_0, x_1, \ldots, x_{n-1}.x_i \\
\text{inv}_{i,j}^n &= \lambda x_0, \ldots, x_i, \ldots, x_j, \ldots, x_{n-1}.\langle x_0, \ldots, x_j, \ldots, x_i, \ldots, x_{n-1}\rangle
\end{aligned}
$$

$$
\begin{aligned}
\text{eval} &= \lambda f, x.f(x) \\
\text{curry} &= \lambda g \lambda x \lambda y.g(x, y) \\
\text{comp} &= \lambda g, f \lambda x.g(f(x)) \\
\text{const} &= \lambda k \lambda x.k \\
\text{fix} &= \lambda f! x.f(x)
\end{aligned}
$$

A TABLE OF COMBINATORS

It is important to note that since we have not typed the variables, these equations are ambiguous: they only become precise when the types are specified. It follows, therefore, that what we find in the table are *schemes* for combinators; there are actually infinitely many distinct combinators corresponding to any one equation depending on how the variables have types chosen for them. Clearly it is better to imagine this variety of combinators than it is to try to notate them with type superscripts.

One interest of combinators is that it is often possible to write expressions without variables — if enough combinators are used. This is sometimes useful, but it can become clumsy. On the other hand, if the same combination occurs over and over, it is sometimes useful to give it a name. This is what we do with, say, *composition* where

$$\text{comp}\ (g, f) = g \circ f.$$

On the one side we have the prefix notation, and on the other, the more common infix notation. With either notation the variable seen in $\lambda x.\ g(f(x))$ has been got rid of. The choice between equivalent notations ought to be based on a desire for readability. □

The reader will have noted that there are some combinators not appearing in Table 5.5. The reason is that combinators like cond, succ, pred, zero, 0 cannot be defined in the pure λ-notation but are specific to domains like T and $\mathbf{N}$; we, thus, have to regard them as primitive. But once they are in hand, a very large number of other functions can be defined from these combined with λ-expressions. The next theorem gives an indication of the possibilities.

Definition (`P0`). The first-projection combinator is the product first projection.

Proof. By definition. ■

Theorem (`P0_apply`). The first-projection combinator recovers the first component of a pair.

Proof. Unfold the definition and apply the projection and pairing laws. ■

Definition (`P1`). The second-projection combinator is the product second projection.

Proof. By definition. ■

Theorem (`P1_apply`). The second-projection combinator recovers the second component of a pair.

Proof. Unfold the definition and apply the projection and pairing laws. ■

Definition (`diagC`). The diagonal combinator pairs the identity with itself.

Proof. By definition. ■

Theorem (`diagC_apply`). The diagonal combinator sends an element to its pair with itself.

Proof. Unfold the definition and apply the pairing and identity laws. ■

Definition (`pairC`). The pairing combinator is the curry of the product identity.

Proof. By definition. ■

Definition (`swapC`). The swap combinator pairs the second projection with the first.

Proof. By definition. ■

Theorem (`swapC_apply`). The swap combinator exchanges the components of a pair.

Proof. Unfold the definition and apply the pairing and projection laws. ■

Definition (`compMapTbl`). The uncurried composition table evaluates the outer function at the value of the inner function on the remaining argument, assembled from projections and evaluations.

Proof. By definition. ■

Definition (`compC`). The composition combinator is the curry of that uncurried composition table.

Proof. By definition. ■

Definition (`constC`). The constant combinator is the curry of the first projection out of a product with a dummy argument domain.

Proof. By definition. ■

Definition (`curryIso`). The curry order isomorphism transports function-space filters through the curry equivalence of approximable maps.

Proof. Compose the function-space filter equivalence with the curry equivalence and the inverse filter equivalence. ■

Definition (`curryC`). The curry combinator is the approximable map induced by that order isomorphism.

Proof. By definition. ■

Definition (`evalC`). The evaluation combinator is the evaluation map of the function space.

Proof. By definition. ■

Definition (`fixC`). The fix combinator of the table is the least-fixed-point combinator on the function space.

Proof. By definition. ■

Definition (`funpairMapTbl`). The uncurried function-pairing table evaluates two function arguments at a shared input and pairs the results.

Proof. By definition. ■

Definition (`funpairC`). The function-pairing combinator is the double curry of that uncurried table.

Proof. By definition. ■

Theorem (`compC_apply`). Composition of function-space elements under the composition combinator evaluates as ordinary composition of the recovered maps.

Proof. Unfold curry and the composition table; simplify with projection, pairing, and evaluation laws. ■

Theorem (`compC_eq_comp`). The map recovered from the composition combinator is the composite of the recovered maps.

Proof. Compare elementwise images via the previous evaluation law. ■

Theorem (`constC_apply`). The constant combinator recovers the constant value at every argument.

Proof. Unfold curry and apply the first-projection law. ■

Theorem (`constC_eq_constMap`). The map recovered from the constant combinator is the constant map.

Proof. Compare elementwise images via the previous evaluation law and the constant-map law. ■

Theorem (`curryC_toApproxMap`). The map recovered from the curry combinator is the curry of the recovered map.

Proof. Unfold the isomorphism-induced map and cancel the filter round trip through the function-space equivalence. ■

Theorem (`curryC_apply`). The curry combinator evaluates by pairing arguments into the original map.

Proof. Rewrite via the previous recovery law and apply the curry evaluation law. ■

Theorem (`evalC_apply`). The evaluation combinator evaluates a function-space element at an argument.

Proof. Unfold the definition and apply the evaluation law. ■

Theorem (`fixC_apply`). The fix combinator of the table recovers the least fixed-point element of the recovered map.

Proof. Unfold the definition and apply the fix-combinator evaluation law. ■

Theorem (`fixC_fixed`). The value of the fix combinator is a fixed point of the recovered map.

Proof. Unfold the definition and apply the fixed-point law for the fix combinator. ■

Theorem (`funpairC_apply`). The function-pairing combinator evaluates to the pair of the two recovered values at a shared argument.

Proof. Unfold the double curry and the pairing table; simplify with projection, pairing, and evaluation laws. ■

Theorem (`funpairC_eq_paired`). The map recovered from the function-pairing combinator is the pairing of the recovered maps.

Proof. Compare elementwise images via the previous evaluation law and the pairing law. ■

Theorem (`pairC_apply`). The pairing combinator evaluates to the pair of its two arguments.

Proof. Unfold curry and apply the identity law. ■

4.6.10 Number-domain recursion schemes

Number-domain recursion schemes: the μ-operator and primitive recursion on pairs of numbers, together with strict identity and projection.

Definition (`kSel`). The construction `kSel` as used in the number-domain / partial-recursive λ-definability development.

Proof. By definition. ■

Definition (`qSel`). The construction `qSel` as used in the number-domain / partial-recursive λ-definability development.

Proof. By definition. ■

Definition (`argX`). The construction `argX` as used in the number-domain / partial-recursive λ-definability development.

Proof. By definition. ■

Definition (`argY`). The construction `argY` as used in the number-domain / partial-recursive λ-definability development.

Proof. By definition. ■

Definition (`muBody`). The construction `muBody` as used in the number-domain / partial-recursive λ-definability development.

Proof. By definition. ■

Definition (`muOp`). The construction `muOp` as used in the number-domain / partial-recursive λ-definability development.

Proof. By definition. ■

Definition (`muRec`). Binary μ-recursion is the least fixed point of the μ-operator on the binary function space.

Proof. By definition. ■

Definition (`muMap`). The unary μ-map searches from zero along the second argument of a binary number-domain map.

Proof. Compose the binary μ-recursion with the pairing of the zero constant and the identity. ■

Definition (`primBody`). The construction `primBody` as used in the number-domain / partial-recursive λ-definability development.

Proof. By definition. ■

Definition (`primOp`). The construction `primOp` as used in the number-domain / partial-recursive λ-definability development.

Proof. By definition. ■

Definition (`primRec`). Binary primitive recursion is the least fixed point of the corresponding primitive-recursion operator.

Proof. By definition. ■

Definition (`strictId`). The strict identity on the number domain, defined via the conditional on the zero-test.

Proof. By definition. ■

Definition (`strictProj0`). The strict first projection on pairs of numbers.

Proof. By definition. ■

Theorem (`T_bot_eq`). The bottom of the truth domain agrees with the two-token bottom element.

Proof. Antisymmetry of the bottoms. ■

Theorem (`muBody_apply`). The stated property of `muBody_apply`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`muMap_natElem`). The stated property of `muMap_natElem`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`muRec_rec`). The stated property of `muRec_rec`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`muRec_bot`). The stated property of `muRec_bot`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`muRec_found`). The stated property of `muRec_found`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`muRec_step`). The stated property of `muRec_step`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`muRec_climb`). The stated property of `muRec_climb`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`muMap_eq_least`). When the predicate first hits zero at n0 with positive values before, the μ-map returns n0.

Proof. Climb the binary μ-recursion from zero and apply the found-zero clause. ■

Theorem (`primBody_apply`). The stated property of `primBody_apply`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`primRec_rec`). The stated property of `primRec_rec`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`primRec_bot`). The stated property of `primRec_bot`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`primRec_succ`). The stated property of `primRec_succ`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`primRec_zero`). The stated property of `primRec_zero`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`strictId_bot`). The stated property of `strictId_bot`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`strictId_natElem`). The stated property of `strictId_natElem`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`strictProj0_apply`). The stated property of `strictProj0_apply`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`strictProj0_bot_left`). The stated property of `strictProj0_bot_left`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`strictProj0_bot_right`). The stated property of `strictProj0_bot_right`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`strictProj0_natElem`). The stated property of `strictProj0_natElem`.
Proof. Follows from the surrounding construct and fixed-point laws. ■

4.6.11 Infinite-product stack combinators

Stack combinators on the infinite product: fold, unfold, push, head, and tail, with the usual head/tail/push laws.

Definition (`fold`). Folding a pair consisting of an element and a sequence into a single sequence is the inverse of the product–sequence isomorphism.

Proof. By definition as the inverse isomorphism. ■

Theorem (`iterProdIso_apply`). The product–sequence isomorphism sends a sequence to the pair of its zeroth component with the sequence of remaining components.

Proof. By the definition of the isomorphism. ■

Definition (`push`). The push combinator places an element at the head of a sequence; it is the same map as fold.

Proof. By definition. ■

Definition (`unfold`). Unfolding a sequence recovers the pair of its head with its tail sequence, via the product–sequence isomorphism.

Proof. By definition as the forward isomorphism. ■

Definition (`head`). The head of a sequence is the first factor of its unfolding.

Proof. Compose the first projection with unfold. ■

Theorem (`head_apply`). Evaluating head at a sequence yields the zeroth component.

Proof. Unpack the composition and the isomorphism, then take the first factor of the resulting pair. ■

Definition (`tail`). The tail of a sequence is the second factor of its unfolding.

Proof. Compose the second projection with unfold. ■

Theorem (`tail_apply`). Evaluating tail at a sequence yields the sequence of components shifted by one.

Proof. Unpack the composition and the isomorphism, then take the second factor of the resulting pair. ■

Theorem (`component_tail`). The n-th component of a tail is the $(n{+}1)$-st component of the original sequence.

Proof. Apply the component formula for sequences built from a function of indices. ■

Theorem (`fold_unfold`). Folding the unfolding of a sequence recovers the sequence.

Proof. The two directions of the product–sequence isomorphism cancel. ■

Theorem (`unfold_fold`). Unfolding the folding of a pair recovers the pair.

Proof. The two directions of the product–sequence isomorphism cancel. ■

Theorem (`push_head_tail`). Pushing the head and tail of a sequence recovers the sequence.

Proof. Reduce push to fold, reassemble the pair of projections from the unfolding, and apply fold–unfold. ■

Theorem (`head_push`). The head of a pushed pair is the pushed element.

Proof. Reduce to unfold–fold and the first projection of a pair. ■

Theorem (`tail_push`). The tail of a pushed pair is the pushed sequence.

Proof. Reduce to unfold–fold and the second projection of a pair. ■

4.6.12 Number-stack argument encoding

Number-stack argument encoding: finite (partial) vectors as sequences over the number domain, together with the λ-definability predicate and the guard/tuple scaffolding used to realize base and composition schemes.

Definition (`optElem`). An optional natural number is interpreted as bottom when absent and as the corresponding number-domain atom when present.

Proof. By definition. ■

Definition (`[U+1D4A9]`). The number-stack is the infinite product of the number domain with itself.

Proof. By definition as the iterated system on the number domain. ■

Definition (`ArgLike`). A sequence is argument-like when every component is either bottom or a number-domain atom.

Proof. By definition. ■

Definition (`argElem`). A finite partial vector is encoded by placing optional atoms in the initial components and bottom thereafter.

Proof. By definition via the sequence constructor. ■

Definition (`vecElem`). A total finite vector is the argument encoding of its pointwise-defined optional values.

Proof. By definition. ■

Definition (`LamDef`). An approximable map λ-defines a partial function when it is strict on argument-like ideals, agrees on defined values, and returns bottom on undefined ones.

Proof. By the structure fields. ■

Theorem (`component_argElem`). The stated property of `component_argElem`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`component_vecElem`). The stated property of `component_vecElem`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Definition (`guard1`). A one-place guard returns bottom when the chosen component is bottom, and otherwise agrees with the guarded map.

Proof. By definition via the conditional on the zero-test of that component. ■

Definition (`oneArg`). A single number is pushed onto the empty stack to form a one-argument sequence.

Proof. Compose push with the pairing of the identity and the constant empty stack. ■

Definition (`strictGuardN`). An n-place strict guard nests one-place guards on the first n components.

Proof. By recursion on n. ■

Definition (`tupleMap`). A tuple of maps into the number domain is assembled by successively pushing their values onto the stack.

Proof. By recursion on the tuple length. ■

Theorem (`T_bot_eq`). The stated property of `T_bot_eq`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`argElem_argLike`). The stated property of `argElem_argLike`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`component_argElem_none`). The stated property of `component_argElem_none`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`component_bot`). The stated property of `component_bot`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`component_push_succ`). The stated property of `component_push_succ`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`component_push_zero`). The stated property of `component_push_zero`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`component_vecElem_lt`). The stated property of `component_vecElem_lt`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`eq_of_component_eq`). The stated property of `eq_of_component_eq`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`guard1_apply`). The stated property of `guard1_apply`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`guard1_bot`). The stated property of `guard1_bot`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`guard1_inner_bot`). The stated property of `guard1_inner_bot`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`guard1_total`). The stated property of `guard1_total`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`lamDef_coe_val`). The stated property of `lamDef_coe_val`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`lamDef_congr`). The stated property of `lamDef_congr`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`mem_mOfFn`). The stated property of `mem_mOfFn`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`oneArg_bot`). The stated property of `oneArg_bot`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`push_natElem_vecElem`). The stated property of `push_natElem_vecElem`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`oneArg_natElem`). The stated property of `oneArg_natElem`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`realizer_value`). The stated property of `realizer_value`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`strictGuardN_strict`). The stated property of `strictGuardN_strict`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`strictGuardN_total`). The stated property of `strictGuardN_total`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`tupleMap_succ`). The stated property of `tupleMap_succ`.
Proof. Follows from the surrounding construct and fixed-point laws. ■
Theorem (`component_tupleMap`). The stated property of `component_tupleMap`.

4.6.13 Partial-recursive scheme realizers

Least-fixed-point realizers on the number-stack for unbounded search and primitive recursion, with their recursion and step lemmas.

Definition (`evalAt`). Evaluation at a fixed stack argument is evaluation of the function-space map at that constant.

Proof. Pair the identity on the function space with the constant argument and compose with evaluation. ■

Definition (`findBody`). The search body returns the head when the predicate vanishes, and otherwise continues at the successor head on the tail.

Proof. By definition via the conditional on the zero-test of the predicate at the current stack. ■

Definition (`findOp`). The search operator is the curry of the search body.

Proof. By definition. ■

Definition (`precBody`). The primitive-recursion body branches on whether the head vanishes, applying the base map on the tail or the step map at the predecessor.

Proof. By definition via the conditional on the zero-test of the head. ■

Definition (`recOp`). The primitive-recursion operator is the curry of the primitive-recursion body.

Proof. By definition. ■

Definition (`recMap`). Primitive recursion is the least fixed point of the primitive-recursion operator.

Proof. By definition. ■

Definition (`rfindZeroPred`). The Mathlib zero-finding predicate for a total vector function is the decision of whether the value at a candidate is zero.

Proof. By definition. ■

Definition (`searchMap`). Unbounded search is the least fixed point of the search operator.

Proof. By definition. ■

Definition (`findMap`). Search from zero prepends a zero head and then applies unbounded search.

Proof. Compose search with the push of the zero constant. ■

Theorem (`evalAt_apply`). The stated property of `evalAt_apply`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`findBody_apply`). The stated property of `findBody_apply`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`findOp_iterElem_zero`). The stated property of `findOp_iterElem_zero`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`iterVal_succ`). The stated property of `iterVal_succ`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`precBody_apply`). The stated property of `precBody_apply`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`findMap_vecElem`). The stated property of `findMap_vecElem`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`recMap_rec`). The stated property of `recMap_rec`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`recMap_eval`). The stated property of `recMap_eval`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`searchMap_rec`). The stated property of `searchMap_rec`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`searchMap_step_found`). The stated property of `searchMap_step_found`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`searchMap_step_next`). The stated property of `searchMap_step_next`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`searchMap_climb`). The stated property of `searchMap_climb`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`toApproxMap_bot`). The stated property of `toApproxMap_bot`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`iterVal_zero`). The stated property of `iterVal_zero`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`iterVal_bot`). The stated property of `iterVal_bot`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`searchMap_diverge`). The stated property of `searchMap_diverge`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

4.6.14 Partial recursive λ-definability

Closure of λ-definability under Mathlib's generators for primitive and partial recursive functions, culminating in the one-variable representation theorem.

Theorem (`lamDef_of_inner`). The stated property of `lamDef_of_inner`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`lamDef_comp`). The stated property of `lamDef_comp`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`lamDef_prec`). The stated property of `lamDef_prec`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`lamDef_primComp`). The stated property of `lamDef_primComp`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`lamDef_rfind`). The stated property of `lamDef_rfind`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`lamDef_total`). The stated property of `lamDef_total`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`lamDef_get`). The stated property of `lamDef_get`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`lamDef_succ`). The stated property of `lamDef_succ`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`lamDef_zero`). The stated property of `lamDef_zero`.

Proof. Follows from the surrounding construct and fixed-point laws. ■

Theorem (`primrec_lamDef`). Every Mathlib primitive-recursive vector function admits a `LamDef` witness.

Proof. Induct on the primitive-recursive generation. ■

Theorem (`partrec_lamDef`). Every Mathlib partial-recursive vector function admits a `LamDef` witness.

Proof. Induct on the partial-recursive generation, using the primitive, composition, and μ-find cases. ■

Theorem (`partrec_one`). Every unary partial recursive function is realized by a strict approximable endomap on the number domain.

Proof. Apply the general `LamDef` existence theorem and compose with the one-argument embedding. ■

4.6.15 Theorem 5.6 — partial recursive functions

THEOREM 5.6. For every partial recursive function $h : \mathbf{N} \to \mathbf{N}$, there is a λ-term τ of type $(\mathbf{N} \to \mathbf{N})$ such that the only constants occurring in τ are

$$\text{cond},\ \text{succ},\ \text{pred},\ \text{zero},\ 0$$

and where if $h(n) = m$, then

$$\tau(n) = m$$

is true; and if $h(n)$ is undefined, then

$$\tau(n) = \bot$$

is true. The equation $\tau(\bot) = \bot$ is also true.

Proof : We have only formulated the theorem for functions of one variable — but to give the proof, it is convenient to pass through functions of any number of (integer) variables. We shall also have to recall the precise definition of the notion of partial recursive function.

It is also convenient to work with (*very*)*strict* functions

$$f : \mathbf{N}^k \to \mathbf{N}.$$

These are functions such that if $n_0, \ldots, n_{k-1} \in \mathbf{N}$ and $n_i = \bot$ for at least one $i < k$, then

$$f(n_0, \ldots, n_{k-1}) = \bot.$$

It is easy to check that compositions of strict functions are strict. It is also easy to see that any *partial* function

$$g : \mathbf{N}^k \to \mathbf{N}$$

extends to a strict (*approximable*) function

$$\bar{g} : \mathbf{N}^k \to \mathbf{N},$$

which takes the same values as g as long as g is defined; otherwise $\bar{g}$ takes the value $\bot$. What we want to show for *partial recursive* g is that the corresponding $\bar{g}$ is defined by a λ - expression.

In the first place we have to check that *primitive recursive* functions have λ - definitions in this sense. We recall that *primitive recursive* functions are generated from certain elementary *starting* functions by multi-variate composition and the scheme of primitive recrusion. The *starting* functions are the constant function with value zero and the "identity" or "projection" functions. For example, $g(n_0, n_1, n_2) = n_1$ for all $n_0, n_1, n_2 \in \mathbf{N}$ is one of the *starting* functions. Now we cannot just use the λ-term

$$\lambda x_0, x_1, x_2.x_1$$

to represent $\bar{g}$, because the function so defined is not strict. But any function in $\mathbf{N}^k \to \mathbf{N}$ can be cut down to a strict function by a simple device. Consider

$$\lambda x.\ \mathrm{cond}(\mathrm{zero}(x), x, x)$$

with x of type $\mathbf{N}$. This is the strict version of the identity function of one argument. The strict projection function of two arguments can be defined by

$$\lambda x_0, x_1.\ \mathrm{cond}(\mathrm{zero}(x_1), x_0, x_0).$$

The one of three arguments by:

$$\lambda x_0, x_1, x_2.\ \mathrm{cond}(\mathrm{zero}(x_0), \mathrm{cond}(\mathrm{zero}(x_2), x_1, x_1), \mathrm{cond}(\mathrm{zero}(x_2), x_1, x_1)).$$

This is not done very elegantly, and the reader can find for himself a general solution based on perhaps a better notation for the required compositions of functions.

As we remarked, strict functions are closed under substitution, and any substitution of a batch of functions into another function can be given by a λ-term, if the various functions can themselves be so defined. It only remains to λ-define functions obtained by primitive recursion. Thus, suppose, for the sake of argument, that

$$\bar{f} : \mathbf{N} \to \mathbf{N} \qquad \text{and} \qquad \bar{g} : \mathbf{N}^3 \to \mathbf{N}$$

are given as total functions with $\bar{f}$ and $\bar{g}$ being λ-definable. From them, we obtain by primitive recursion $\bar{h} : \mathbf{N}^2 \to \mathbf{N}$ where

$$\bar{h}(0, m) = \bar{f}(m),$$

$$\bar{h}(n+1, m) = \bar{g}(n, m, \bar{h}(n, m))$$

for all $n, m \in \mathbf{N}$. The λ-term defining $\bar{h}$ is

$$!k\ \lambda x, y.\ \mathrm{cond}(\mathrm{zero}(x), \bar{f}(y), \bar{g}(\mathrm{pred}(x), y, k(\mathrm{pred}(x), y))).$$

Here we have had to use the fixed-point operator on a variable k of type $(\mathbf{N}^2 \to \mathbf{N})$. The variables x, y are of type $\mathbf{N}$ and the cond-construction puts the two traditional equations into two clauses of one expression. It is easy to see that the fixed-point function *is* strict and is nothing more than $\bar{h}$.

That completes the representation of *primitive recursive* functions. To obtain the *partial recursive* functions, the idea is to use the so-called μ-scheme (least number operator) and, further, to close up under substitution. We need only treat the μ-scheme. Suppose, by way of example, $f(n, m)$ is given as a

primitive recursive function. We then define h (generally, a partial function) by

$$h(m) = \text{the least } n \text{ where } f(n, m) = 0.$$

This is often written

$$h(m) = \mu n.\ f(n, m) = 0.$$

Supposing, as we may, $\bar{f}$ is λ-definable, we introduce first

$$\bar{g} = !g\, \lambda x, y.\, \mathrm{cond}(\mathrm{zero}(\bar{f}(x,y)), x, g(\mathrm{succ}(x), y)).$$

Then $\bar{h} = \lambda y.\, \bar{g}(0, y)$. This is easily seen to be strict. Also easy to see is that if $h(m)$ is defined, then $\bar{g}(0, m) = h(m)$. But, if $h(m)$ is not defined, it takes some argument to make sure that the least fixed-point construction forces $\bar{g}(0, m) = \bot$. However, the argument is not very difficult. □

What is *not* said in 5.6 is that every λ-term defines a partial recursive function. This is true (with suitable control over the constants and types in the expression), but the proof requires a full analysis of computability properties of domain constructions. This is the topic of Lecture VII.

It should be remarked that the types of variables needed for the proof of 5.6 never get very high. In fact, types like N, N^k, and $(N^k \to N)$ were the only ones needed (with perhaps T thrown in also).

Recursion on N was the topic of 5.6; further examples of recursion on other domains are included in the exercises.

The binary μ- and primitive-recursion schemes on the number domain are with the number-domain recursion schemes peer. The `LamDef` completeness development and the one-variable representation theorem are with the partial recursive λ-definability peer.

Theorem (`theorem_56`). Every unary partial recursive function is realized by a strict approximable endomap on the number domain that returns numerals on defined values and bottom on undefined values and at bottom.

Proof. Invoke the one-variable partial-recursive λ-definability theorem. ■

4.6.16 Multi-argument λ-abstraction

Multi-argument λ-abstraction and application via iterated curry and uncurry, together with the pairing reconstruction used to simulate simultaneous arguments.

Definition (`curry3`). Ternary curry is the double curry of a map on a nested product.

Proof. By definition. ■

Theorem (`app_two_args`). Applying a binary map to a pair equals evaluating its curry at the two components in succession.

Proof. The curry evaluation law. ■

Theorem (`curry3_apply`). A thrice-curried map evaluates by nesting three arguments as a pair of pairs.

Proof. Apply the curry evaluation law twice. ■

Theorem (`lam_two_vars`). The single-variable λ-abstraction of a binary map recovers the map on pairs when applied to both arguments.

Proof. The curry evaluation law. ■

Theorem (`surjective_pairing`). Pairing the two projections of a product element recovers that element.

Proof. Unpack the projections and reassemble with the pairing identity. ■

Theorem (`uncurry_apply`). Uncurry evaluates by applying the curried map to the two components of a pair.

Proof. Expand uncurry as evaluation against the paired projections. ■

Theorem (`uncurry_lam_two_vars`). Uncurry is a left inverse of curry on binary maps.

Proof. The standard uncurry–curry law. ■

4.6.17 Exercise 5.7 — currying the lambda notation

Find definitions of

$$\lambda x, y.\, \tau \quad \text{and} \quad \sigma(x, y)$$

which use only λv with one variable and applications only to one argument at a time. Note that use must be made of the combinators p_0, p_1, pair. Generalize the result to functions of many variables.

The development is with the multi-argument λ-abstraction peer.

Theorem (`example_507`). Binary λ-abstraction and application are curry and successive evaluation; uncurry inverts curry; pairing is recovered from its projections; ternary curry evaluates by nested pairs.

Proof. Assemble `lam_two_vars`, `app_two_args`, `uncurry_lam_two_vars`, `surjective_pairing`, and `curry3_apply` from the multi-argument λ peer. ■

4.6.18 Combinatory completeness

Combinatory completeness: I, K, and S realize every polynomial λ-term via bracket abstraction.

Definition (`Dom`). A domain package is a carrier type with a neighbourhood system.

Proof. By definition. ■

Abbreviation (`Dom.arrow`). The function-space domain between two packaged domains.

Proof. By definition. ■

Definition (`CL`). Combinatory terms are constants or applications.

Proof. By definition. ■

Definition (`CL.denote`). Denotation of a combinatory term evaluates applications via approximable maps.

Proof. By definition. ■

Definition (`Poly`). Polynomials over a parameter domain are variables, constants, or applications.

Proof. By definition. ■

Definition (`Poly.denote`). Denotation of a polynomial is a map from the parameter element.

Proof. By definition. ■

Definition (`Ielem`). The I combinator is the identity map as a filter element.

Proof. By definition. ■

Definition (`Kelem`). The K combinator is the curry of the first projection.

Proof. By definition. ■

Definition (`Sbody`). The S-body evaluates two curried maps at a shared argument.

Proof. By definition. ■

Definition (`Smap`). The S combinator map is the double curry of the S-body.
Proof. By definition. ■
Definition (`Selem`). The S combinator as a filter element on packaged domains.
Proof. By definition. ■
Definition (`bracket`). Bracket abstraction translates a polynomial into an I/K/S combinatory term.
Proof. By definition. ■
Theorem (`Smap_apply`). The S map evaluates by applying both branches at the shared argument.
Proof. Follows from the surrounding construct and evaluation laws. ■
Theorem (`toApproxMap_toFilter`). toApproxMap inverts toFilter on approximable maps.
Proof. Follows from the surrounding construct and evaluation laws. ■
Theorem (`Ielem_apply`). I acts as the identity.
Proof. Follows from the surrounding construct and evaluation laws. ■
Theorem (`Kelem_apply`). K returns its first argument.
Proof. Follows from the surrounding construct and evaluation laws. ■
Theorem (`Selem_apply`). S acts by the S-map evaluation law.
Proof. Follows from the surrounding construct and evaluation laws. ■
Theorem (`bracket_spec`). Bracket abstraction preserves denotation on every argument.
Proof. Induction on the polynomial, using the I, K, and S evaluation laws. ■

4.6.20 Exercise 5.9 — common fixed points

Suppose that $f, g : \mathcal{D} \to \mathcal{D}$ are approximable and $f \circ g = g \circ f$. Show that f and g have a *least common fixed point* $x = f(x) = g(x)$. (Hint: Refer back to Exercise 4.20.) If in addition $f(\bot) = g(\bot)$, show that $\mathrm{fix}(f) = \mathrm{fix}(g)$. In particular, will $\mathrm{fix}(f) = \mathrm{fix}(f^2)$? What if we only assume $f \circ g = g^2 \circ f$?

The development uses the commuting-fixed-point lemmas packaged with Exercise 4.11.

Theorem (`example_509`). Commuting endomaps share a least common fixed point; if they also agree at bottom then their least fixed points coincide; in particular the least fixed point of a map equals that of its square.

Proof. Assemble the commuting least-common-fixed-point law, the equal-bottoms uniqueness law, and the iterate-twice law from the Exercise 4.11 development. ■

4.6.21 Smash product

Smash product of neighbourhood systems, strict function spaces, and the curry isomorphism with smash.

Definition (`SmashProper`). The construction `SmashProper` as used in the smash-product development.

Proof. By definition. ■

Theorem (`inter_ne_master_left`). The stated property of `inter_ne_master_left`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`inter_ne_master_right`). The stated property of `inter_ne_master_right`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`smash`). The smash product of two neighbourhood systems consists of the joined masters together with unions of proper neighbourhoods from each factor.

Proof. The master and intersection axioms follow from those of the factors, using properness of the summands. ■

Theorem (`smash_master`). The stated property of `smash_master`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smash_mem_bot`). The stated property of `smash_mem_bot`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smash_mem_proper`). The stated property of `smash_mem_proper`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`smashPair`). The construction `smashPair` as used in the smash-product development.

Proof. By definition. ■

Theorem (`mem_smashPair`). The stated property of `mem_smashPair`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`IsStrict`). A map is strict when it sends bottom to bottom in the sense that proper neighbourhoods cannot pull back only the master.

Proof. By definition. ■

Abbreviation (`StrictMap`). A strict map is an approximable map that is strict.

Proof. By definition. ■

Theorem (`eq_bot_of_no_proper`). The stated property of `eq_bot_of_no_proper`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`exists_proper_of_ne_bot`). The stated property of `exists_proper_of_ne_bot`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`isStrict_constBot`). The stated property of `isStrict_constBot`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`isStrict_iff_apply_bot`). The stated property of `isStrict_iff_apply_bot`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`IsStrict.mono`). The stated property of `IsStrict.mono`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`principal_master_eq_bot`). The stated property of `principal_master_eq_bot`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smashPair_bot_left`). The stated property of `smashPair_bot_left`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smashPair_bot_right`). The stated property of `smashPair_bot_right`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smashPair_eq_bot_iff`). The stated property of `smashPair_eq_bot_iff`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smashPair_mono`). The stated property of `smashPair_mono`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`sstep`). The construction `sstep` as used in the smash-product development.

Proof. By definition. ■

Theorem (`mem_sstep`). The stated property of `mem_sstep`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`sstepFun`). The construction `sstepFun` as used in the smash-product development.

Proof. By definition. ■

Theorem (`mem_sstepFun`). The stated property of `mem_sstepFun`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstepFun_nil`). The stated property of `sstepFun_nil`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstepFun_append`). The stated property of `sstepFun_append`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstepFun_cons`). The stated property of `sstepFun_cons`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstepFun_singleton`). The stated property of `sstepFun_singleton`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstep_master_eq`). The stated property of `sstep_master_eq`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstep_inter_right`). The stated property of `sstep_inter_right`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstep_subset`). The stated property of `sstep_subset`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`strictFun`). The strict function space has neighbourhoods generated by finite lists of proper relation steps between strict maps.

Proof. By definition as a neighbourhood system on strict maps. ■

Theorem (`strictFun_master`). The stated property of `strictFun_master`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstepFun_up_closed`). The stated property of `sstepFun_up_closed`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstep_mem_of_mem`). The stated property of `sstep_mem_of_mem`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`mem_sstepFun_iff`). The stated property of `mem_sstepFun_iff`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`strictFun_mem_iff`). The stated property of `strictFun_mem_iff`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`strictFun_mem_inter`). The stated property of `strictFun_mem_inter`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`strictFun_mem_up_closed`). The stated property of `strictFun_mem_up_closed`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`toStrictMap`). The construction `toStrictMap` as used in the smash-product development.

Proof. By definition. ■

Theorem (`toStrictMap_rel`). The stated property of `toStrictMap_rel`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`toStrictFilter`). The construction `toStrictFilter` as used in the smash-product development.

Proof. By definition. ■

Theorem (`mem_toStrictFilter`). The stated property of `mem_toStrictFilter`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`rel_sstepFun_iff`). The stated property of `rel_sstepFun_iff`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smashPair_principal_apply`). The stated property of `smashPair_principal_apply`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`smashSection`). The construction `smashSection` as used in the smash-product development.

Proof. By definition. ■

Theorem (`isStrict_smashSection`). The stated property of `isStrict_smashSection`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smashSection_mono`). The stated property of `smashSection_mono`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smashSection_rel`). The stated property of `smashSection_rel`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`smashCurryMap`). The construction `smashCurryMap` as used in the smash-product development.

Proof. By definition. ■

Theorem (`smash_mem_prodNbhd_form`). The stated property of `smash_mem_prodNbhd_form`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`smashUncurryMap`). The construction `smashUncurryMap` as used in the smash-product development.

Proof. By definition. ■

Theorem (`smashUncurry_curry`). The stated property of `smashUncurry_curry`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`sstep_cod_master`). The stated property of `sstep_cod_master`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`section_uncurry_rel`). The stated property of `section_uncurry_rel`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smashCurry_uncurry`). The stated property of `smashCurry_uncurry`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Definition (`smashCurryEquiv`). Currying against the smash product yields an order isomorphism between strict maps out of smash and strict maps into the strict function space.

Proof. The forward and reverse maps are smashCurryMap and smashUncurryMap; the inverse laws and relation preservation supply the isomorphism. ■

Definition (`strictFunEquiv`). The construction `strictFunEquiv` as used in the smash-product development.

Proof. By definition. ■

Theorem (`isStrict_idMap`). The stated property of `isStrict_idMap`.

Proof. Follows from the surrounding smash and strict-map laws. ■

Theorem (`smash_mem_iff`). Membership in the smash product is either the joined master or a proper smash neighbourhood.

Proof. By definition. ■

4.6.22 Exercise 5.10 — smash product

Suppose $\mathcal{D}_0$ and $\mathcal{D}_1$ are neighbourhood systems over disjoint sets Δ_0 and Δ_1. Define the *smash product* $\mathcal{D}_0 \otimes \mathcal{D}_1$ with neighbourhoods

$$\{\Delta_0 \cup \Delta_1\} \cup \{X \cup Y \mid X \in \mathcal{D}_0 \setminus \{\Delta_0\} \text{ and } Y \in \mathcal{D}_1 \setminus \{\Delta_1\}\}.$$

Show that this *is* a neighbourhood system. Define $(\mathcal{D}_0 \to_\perp \mathcal{D}_1)$ so that $|\mathcal{D}_0 \to_\perp \mathcal{D}_1|$ consists exactly of the *strict functions*. By introducing appropriate combinators, show that

$$(\mathcal{D}_0 \to_\perp (\mathcal{D}_1 \to_\perp \mathcal{D}_2)) \quad \text{and} \quad ((\mathcal{D}_0 \otimes \mathcal{D}_1) \to_\perp \mathcal{D}_2)$$

are isomorphic.

The development is with the smash product peer.

Theorem (`example_510`). Membership in the smash product is the joined master or a proper smash neighbourhood, and currying yields an order isomorphism between strict maps out of smash and strict maps into the strict function space.

Proof. The smash membership characterisation and the smash–curry equivalence from the smash-product peer. ■

4.6.23 Diagonal and map stacks

Diagonal and componentwise map combinators on infinite-product stacks, obtained by fixed-point recursion from the stack push.

Definition (`Arg`). The argument domain for the map combinator is the product of a stack of endomaps with the underlying domain.

Proof. By definition. ■

Definition (`diag`). The diagonal combinator is the fixed point of push, curried in the element being stacked.

Proof. By definition. ■

Definition (`mapBody`). The body of the map recursion pushes the head map applied to the element onto the recursive map of the tail.

Proof. By definition. ■

Definition (`mapOp`). The map operator is the curry of the map body.

Proof. By definition. ■

Definition (`mapMap`). The map combinator is the fixed point of the map operator, viewed as an approximable map.

Proof. By definition. ■

Theorem (`diag_rec`). The diagonal of an element equals the push of that element onto its own diagonal.

Proof. Unpack the fixed-point and curry evaluation laws for push. ■

Theorem (`mapBody_apply`). The map body at a functional and a stack–element pair pushes the head map on the element onto the functional applied to the tail stack with the same element.

Proof. Expand the body through projections, evaluation, and pairing. ■

Theorem (`map_rec`). Mapping a stack of maps on an element equals pushing the head application onto the map of the tail.

Proof. The fixed-point law for the map operator together with the map-body evaluation. ■

Theorem (`component_diag`). Every component of the diagonal of an element is that element.

Proof. Induct on the index, using the diagonal recursion and the head/tail laws for push. ■

Theorem (`component_map`). The nth component of mapping a stack of maps on an element is the nth map applied to that element.

Proof. Induct on the index, using the map recursion and the head/tail laws for push. ■

4.6.24 Exercise 5.11 — stack combinators

For any domain $\mathcal{D}$ we may regard $\mathcal{D}^\infty$ as consisting of (bottomless) *stacks* of elements of $\mathcal{D}$. With this image in mind, define appropriate combinators with the obvious meanings:

$$\{\mathrm{head} : \mathcal{D}^\infty \to \mathcal{D}\}; \quad \{\mathrm{tail} : \mathcal{D}^\infty \to \mathcal{D}^\infty\}; \quad \{\mathrm{push} : \mathcal{D} \times \mathcal{D}^\infty \to \mathcal{D}^\infty\}.$$

Using the fixed-point theorem argue that there is a combinator

$$\{\mathrm{diag} : \mathcal{D} \to \mathcal{D}^\infty\}$$

where for all $x \in |\mathcal{D}|$ we have

$$\mathrm{diag}(x) = \langle x \rangle_{n=0}^{\infty}.$$

(Hint: Try a recursive definition, say

$$\mathrm{diag}(x) = \mathrm{push}(x, \mathrm{diag}(x)),$$

but be sure to prove *all* terms of $\mathrm{diag}(x)$ equal x.) Also introduce by an appropriate recursion a combinator

$$\{\mathrm{map} : (D \to D)^\infty \times D \to D^\infty\}$$

where for elements of the suitable types:

$$\mathrm{map}(\langle f_n \rangle_{n=0}^{\infty}, x) = \langle f_n(x) \rangle_{n=0}^{\infty}.$$

The stack combinators are with the infinite-product stack peer; the diagonal and map recursion are with the diagonal and map stacks peer.

Theorem (`example_511`). Every component of the diagonal of an element is that element, and every component of mapping a stack of maps on an element is the corresponding map applied to that element.

Proof. The component laws for the diagonal and map combinators from the diagonal-and-map peer. ■

4.6.25 While combinator

The while combinator as the least fixed point of a conditional body that either recurses after applying the step map or returns the current element.

Definition (`bodyMap`). The while body conditions on the predicate at the current element, pairing the recursive application after the step with the current element.

Proof. By definition. ■

Definition (`Wop`). The while operator is the curry of the while body.

Proof. By definition. ■

Definition (`whileFix`). The while fixed point is the least fixed point of the while operator.

Proof. By definition. ■

Definition (`whileMap`). The while combinator is that fixed point viewed as an approximable map.

Proof. By definition. ■

Theorem (`bodyMap_apply`). The while body at a functional and an element conditions on the predicate, pairing the functional on the step with the element.

Proof. Expand through projections, evaluation, and pairing. ■

Theorem (`Wop_apply`). Applying the while operator at a functional recovers the conditional body.

Proof. Curry evaluation with the body law. ■

Theorem (`whileMap_least`). Any functional satisfying the while recursion dominates the while fixed point.

Proof. The least-fixed-point characterisation of the while operator. ■

Theorem (`whileMap_rec`). While satisfies the conditional recursion at every element.

Proof. The fixed-point law for the while operator. ■

Theorem (`whileMap_bot`). When the predicate is bottom, while returns bottom.

Proof. The recursion together with the bottom case of conditional. ■

Theorem (`whileMap_false`). When the predicate is false, while returns the current element.

Proof. The recursion together with the false case of conditional. ■

Theorem (`whileMap_true`). When the predicate is true, while recurses after the step map.

Proof. The recursion together with the true case of conditional. ■

On any domain D introduce (as a least fixed point) a combinator

$$\mathrm{while} : (D \to T) \times (D \to D) \to (D \to D)$$

by the recursion

$$\mathrm{while}(p, f)(x) = \mathrm{cond}(p(x), \mathrm{while}(p, f)(f(x)), x).$$

Prove that

$$\mathrm{while}(p, \mathrm{while}(p, f)) = \mathrm{while}(p, f).$$

Show how while could have been used to obtain the least number operator mentioned in the proof of 5.6. Generalize the idea to define a combinator

$$\{\mathrm{find} : D^{\infty} \times (D \to T) \to D\}$$

with the meaning "find the first term of the sequence (if any) which satisfies the given precicate."

The development is with the while combinator peer.

Theorem (`example_512`). The while combinator satisfies the conditional recursion, and the three truth-value cases return bottom, the current element, or a recursive call after the step, respectively.

Proof. The while recursion and case laws from the while-combinator peer. ■

4.6.27 Natural-number pairing

Cantor pairing of natural numbers via triangular numbers, with the diagonal-step recurrence and a two-sided inverse.

Definition (`nextCell`). The next cell on the antidiagonal enumeration steps left-and-up, or wraps to the next antidiagonal.

Proof. By definition. ■

Definition (`tri`). The kth triangular number is $k(k+1)/2$.

Proof. By definition. ■

Definition (`num`). The pairing of n and m is the triangular number of their sum plus m.

Proof. By definition. ■

Definition (`numP`). Pairing on a product is pairing of the two components.

Proof. By definition. ■

Theorem (`num_succ_right`). Incrementing the second argument equals stepping left on the antidiagonal and adding one.

Proof. Compare triangular numbers after rewriting the sum. ■

Theorem (`num_zero_zero`). The origin pairs to zero.

Proof. Immediate from the definitions. ■

Theorem (`two_dvd_mul_succ`). Twice divides the product of a number and its successor.

Proof. Induction on the number. ■

Theorem (`tri_mul_two`). Twice a triangular number recovers the product of the index with its successor.

Proof. Cancel the division using the previous divisibility. ■

Theorem (`tri_succ`). The next triangular number adds the next index.

Proof. Compare doubles of both sides. ■

Theorem (`num_lt_tri_succ`). A pairing lies strictly below the next triangular number after its antidiagonal.

Proof. Expand via the triangular successor law. ■

Theorem (`num_succ_left`). Starting a new antidiagonal equals wrapping from the previous row and adding one.

Proof. Expand via the triangular successor law. ■

Theorem (`numP_nextCell`). Stepping to the next cell increments the pairing value by one.

Proof. Case on the first coordinate and apply the two successor laws. ■

Theorem (`tri_le_succ`). Triangular numbers are monotone in the successor.

Proof. The triangular successor law. ■

Theorem (`tri_mono`). Triangular numbers are monotone.

Proof. Induction along the inequality. ■

Theorem (`num_injective`). The pairing on products is injective.

Proof. Equal pairings force equal antidiagonals by the triangular bounds, then equal second coordinates. ■

Definition (`unnum`). The inverse enumeration walks the next-cell map from the origin.

Proof. By definition. ■

Theorem (`numP_unnum`). Pairing after unpairing recovers the number.

Proof. Induction, using the next-cell increment. ■

Theorem (`unnum_numP`). Unpairing after pairing recovers the cell.

Proof. Injectivity of pairing with the previous round-trip. ■

4.6.28 Exercise 5.13 — pairing function on numbers

Prove the existence of a one-one function $\mathrm{num} : \mathbf{N} \times \mathbf{N} \to \mathbf{N}$ such that

$$\mathrm{num}(0,0) = 0;$$

$$\mathrm{num}(n, m+1) = \mathrm{num}(n+1, m) + 1;$$

$$\mathrm{num}(n+1, 0) = \mathrm{num}(0, n) + 1.$$

Draw a picture (i.e. an infinite matrix) for the function and find a closed form for its values, if possible. Use the function to prove the isomorphism of the domains

$$P\mathbf{N},\ P(\mathbf{N} \times \mathbf{N}),\ P\mathbf{N} \times P\mathbf{N}.$$

The pairing development is with the natural-number pairing peer; the powerset isomorphisms continue in Exercise 5.13 (powerset).

Theorem (`example_513`). The Cantor pairing sends the origin to zero, obeys the two antidiagonal successor laws, and is inverted by the next-cell enumeration.

Proof. The zero, successor, and inverse laws from the natural-number pairing peer. ■

4.6.29 Powerset isomorphisms

Order isomorphisms among power sets of the naturals, of pairs of naturals, and of the product of two power sets, induced by the Cantor pairing and the sum–product equivalence.

Definition (`numEquiv`). The Cantor pairing and its inverse form an equivalence between pairs of naturals and naturals.

Proof. The two-sided inverse laws for the pairing. ■

Theorem (`numEquiv_apply`). The equivalence on a pair is the pairing of its components.

Proof. By definition. ■

Definition (`setCongr`). An equivalence of types induces an order isomorphism of power sets by direct image.

Proof. Direct and inverse images are mutual inverses; inclusion is preserved both ways by injectivity. ■

Definition (`PN_orderIso_PNN`). Power sets of naturals are order-isomorphic to power sets of pairs via the inverse pairing.

Proof. Apply the set congruence to the symmetric pairing equivalence. ■

Definition (`PN_orderIso_prod`). Power sets of naturals are order-isomorphic to a product of two power sets via the sum–natural equivalence.

Proof. Compose the set congruence of the sum equivalence with the sum–product isomorphism of sets. ■

Definition (`PNN_orderIso_prod`). Power sets of pairs are order-isomorphic to a product of two power sets.

Proof. Transport the previous isomorphism along the pairing isomorphism. ■

4.6.31 Set graphs

Tagging finite sequences by iterated Cantor pairing, and the Fun/Graph correspondence between subsets of naturals and approximable set-maps.

Definition (`tag`). Tagging a list against a payload iterates the Cantor pairing with successors on the list entries and zero on the empty list.

Proof. By definition. ■

Theorem (`tag_nil`). Tagging the empty list is pairing zero with the payload.

Proof. By definition. ■

Theorem (`tag_cons`). Tagging a cons cell pairs the successor of the head with the tag of the tail.

Proof. By definition. ■

Definition (`entries`). The entry set of a list is the set of its members.

Proof. By definition. ■

Theorem (`mem_entries`). Membership in the entry set is list membership.

Proof. By definition. ■

Definition (`Fun`). The function of a code set sends an input set to those payloads whose tagged finite witnesses lie in the code and whose entries lie in the input.

Proof. By definition. ■

Definition (`Graph`). The graph of a set-map collects tags of finite witnesses whose payload lies in the map of their entry set.

Proof. By definition. ■

Definition (`IsApprox`). A set-map is approximable when it is monotone and every output has a finite witness from the input.

Proof. By definition. ■

Theorem (`Fun_isApprox`). The function of any code is approximable.

Proof. Monotonicity uses input enlargement; finite witnesses are the same lists used in the membership. ■

Theorem (`Fun_mono`). Enlarging the code or the input enlarges the function value.

Proof. Transport the finite witness. ■

Theorem (`num_succ_left_gt`). A second component is strictly below a pairing whose first component is a successor.

Proof. Expand via the triangular successor. ■

Theorem (`tag_injective`). Equal tags force equal lists and equal payloads.

Proof. Induction on the first list, using injectivity of pairing. ■

Theorem (`Fun_Graph`). For an approximable set-map, the function of its graph recovers the map.

Proof. One inclusion uses injectivity of tags and monotonicity; the other uses the finite-witness property. ■

Theorem (`tag_surjective`). Every natural is a tag of some list and payload.

Proof. Strong induction via unpairing and the strict decrease of the second component on successors. ■

Theorem (`id_le_Graph_Fun`). Every code is contained in the graph of its function.

Proof. Surjectivity of tags supplies a witness whose membership is preserved. ■

4.6.32 Exercise 5.14 — functions as graphs

Show that there are approximable mappings

$$\mathrm{graph} : (P\mathbf{N} \to P\mathbf{N}) \to P\mathbf{N} \quad \text{and} \quad \mathrm{fun} : P\mathbf{N} \to (P\mathbf{N} \to P\mathbf{N}),$$

where we have

$$\mathrm{fun} \circ \mathrm{graph} = \lambda f.\, f, \quad \text{and} \quad \mathrm{graph} \circ \mathrm{fun} \supseteq \lambda x.\, x.$$

(Hint: Using the notation

$$[n_0, n_1, \ldots, n_k] = \mathrm{num}(n_0, [n_1, \ldots, n_k])$$

two such combinators can be given by formulae

$$\mathrm{fun}(u)(x) = \{m \mid \exists n_0, \ldots, n_{k-1} \in x.\, [n_0 + 1, \ldots, n_{k-1} + 1, 0, m] \in u\}$$

$$\mathrm{graph}(f) = \{[n_0 + 1, \ldots, n_{k-1} + 1, 0, m] \mid m \in f(\{n_0, \ldots, n_{k-1}\})\}$$

where k is variable — meaning all finite sequences are to be considered.)

The development is with the set graphs peer.

Theorem (`example_514`). The function of any code is approximable; for approximable set-maps, the function of the graph recovers the map; and every code sits inside the graph of its function.

Proof. The Fun/Graph laws from the set-graphs peer. ■

4.6.33 Language star

Kleene star of languages in a monoid, Arden's least-fixed-point law, and Park's least solution of the two-variable language equations.

Definition (`kpow`). The nth power of a set of monoid elements is the unit for zero and left multiplication by the set for successors.

Proof. By definition. ■

Theorem (`kpow_zero`). The zeroth power is the unit set.

Proof. By definition. ■

Theorem (`kpow_succ`). The successor power left-multiplies by the set.

Proof. By definition. ■

Definition (`G`). The Arden operator left-multiplies by a fixed set and unions a fixed remainder.

Proof. By definition. ■

Definition (`star`). The star of a set collects all finite powers.

Proof. By definition. ■

Definition (`parkA`). Park's A coefficient is a union b times star of a times b.

Proof. By definition. ■

Definition (`parkC`). Park's C coefficient is c union b times star of a times d.

Proof. By definition. ■

Definition (`parkX`). Park's x-solution is the star of A times C.

Proof. By definition. ■

Definition (`parkY`). Park's y-solution is the star of a times the union of b times x with d.

Proof. By definition. ■

Theorem (`mem_kpow_singleton`). Membership in a power of a singleton is equality with the corresponding power of the generator.

Proof. Induction on the exponent. ■

Theorem (`mem_star`). Membership in the star is existence of a power membership.

Proof. By definition. ■

Theorem (`mem_star_singleton`). Membership in the star of a singleton is equality with some power of the generator.

Proof. Transport the singleton power characterisation. ■

Theorem (`smul_assoc`). Pointwise multiplication of sets is associative.

Proof. Unpack products and reassociate the monoid multiplication. ■

Theorem (`smul_union`). Left multiplication distributes over union.

Proof. Case on which summand supplies the right factor. ■

Theorem (`star_eq`). The star equals the unit union the set times the star.

Proof. Compare powers with the unit and successor cases. ■

Theorem (`star_mul_subset_prefixed`). If a set absorbs left multiplication by z after union with v, then star of z times v sits inside it.

Proof. Induct on the power, using absorption of left multiplication. ■

Theorem (`sunion_mul`). Right multiplication distributes over union.

Proof. Case on which summand supplies the left factor. ■

Theorem (`star_mul_isFixed`). Star of z times v is a fixed point of the Arden operator for z and v.

Proof. Expand the star equation and redistribute. ■

Theorem (`arden`). The least fixed point of the Arden operator is star of z times v.

Proof. The star product is a fixed point and least among prefixed points. ■

Theorem (`parkX_eq`). Park's x satisfies the first language equation.

Proof. The star fixed-point law for Park's A and C, redistributed. ■

Theorem (`parkY_eq`). Park's y satisfies the second language equation.

Proof. The star fixed-point law for a against the y-body, redistributed. ■

Theorem (`park_least`). Any solution of the two language equations dominates Park's solution.

Proof. Prefixedness of the Park coefficients under any solution, then Arden. ■

Theorem (`park_solves`). Park's pair solves the two language equations.

Proof. The two Park equation laws. ■

Theorem (`part1`). For singletons, the least fixed point of left multiplication by e union $\{e'\}$ is the star of $\{e\}$ times $\{e'\}$.

Proof. Arden's lemma on singletons. ■

Theorem (`part1_freeMonoid`). The singleton Arden law specialises to the free monoid on booleans.

Proof. Specialise the singleton Arden law. ■

4.6.34 Exercise 5.15 — star of a word

(For algebraists.) We can regard $\langle \{0,1\}^*, \Lambda, \cdot \rangle$ as the free semigroup on two generators 0 and 1. The powerset $P\{0,1\}^*$ is taken as a domain as in Exercise 4.17. For "words" $e \in \{0,1\}^*$ define

$$e^* = \{\Lambda, e, e^2, e^3, \ldots, e^n, \ldots\}.$$

Show that the least fixed point of

$$z = \{e\} \cdot z \cup \{e'\}$$

in $P\{0,1\}^*$ is $z = e^* \cdot \{e'\}$.

Show further (as suggested by David Park) that the least solution of

$$x = a \cdot x \cup b \cdot y \cup c,$$
$$y = b \cdot x \cup a \cdot y \cup d$$

has

$$x = (a \cup b \cdot a^* \cdot b)^* \cdot (c \cup b \cdot a^* \cdot d),$$

where the $\{\cdot\}$ has been dropped off $\{a\}$, $\{b\}$ etc., and where the *-notation has been extended to the whole domain, so that $z^* = \Lambda \cup z^* \cdot z$.

(Hint: Apply 5.3.)

The development is with the language star peer.

Theorem (`example_515`). On the free monoid of boolean words, the least fixed point of left multiplication by a singleton union another singleton is the star product; Park's pair solves the two language equations and is least among solutions.

Proof. The free-monoid Arden law and the Park solution/leastness laws from the language-star peer. ■

4.6.35 Sequence negation and merge

Negation, doubling, merge, and the Thue–Morse sequence on the domain of binary streams.

Definition (`flip`). Bitwise negation of a finite boolean string.

Proof. By definition. ■

Theorem (`flip_nil`). The named base or successor case.

Proof. By unfolding the definition. ■

Theorem (`flip_cons`). The named base or successor case.

Proof. By unfolding the definition. ■

Theorem (`flip_flip`). The named law for flip, double, or tail.

Proof. Unfold the string operations and the map laws. ■

Definition (`double`). Doubling inserts a copy of each bit.

Proof. By definition. ■

Theorem (`double_nil`). The named base or successor case.

Proof. By unfolding the definition. ■

Theorem (`double_cons`). The named base or successor case.

Proof. By unfolding the definition. ■

Theorem (`double_append`). The named comparison or prefix law for stream principals.

Proof. Unpack principal order via cones and singletons. ■

Theorem (`double_prefix`). The named comparison or prefix law for stream principals.

Proof. Unpack principal order via cones and singletons. ■

Theorem (`flip_prefix`). The named comparison or prefix law for stream principals.

Proof. Unpack principal order via cones and singletons. ■

Theorem (`not_strElem_le_strBot`). The named comparison or prefix law for stream principals.

Proof. Unpack principal order via cones and singletons. ■

Theorem (`strBot_le_strBot_iff`). The named comparison or prefix law for stream principals.

Proof. Unpack principal order via cones and singletons. ■

Theorem (`strBot_le_strElem_iff`). The named comparison or prefix law for stream principals.

Proof. Unpack principal order via cones and singletons. ■

Theorem (`strElem_le_strElem_iff`). The named comparison or prefix law for stream principals.

Proof. Unpack principal order via cones and singletons. ■

Definition (`tailSing`). The singular tail of a string, bottom on empty.

Proof. By definition. ■
Theorem (`tail_hsing`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Theorem (`tail_prefix`). The named comparison or prefix law for stream principals.
Proof. Unpack principal order via cones and singletons. ■
Theorem (`tail_hcone`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Definition (`tailMap`). The approximable tail map on the stream domain.
Proof. By definition. ■
Theorem (`tailMap_strBot`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Theorem (`tailMap_strElem`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Theorem (`neg_hcone`). The named law for stream negation.
Proof. Use the approximable-map presentation of negation. ■
Theorem (`neg_hsing`). The named law for stream negation.
Proof. Use the approximable-map presentation of negation. ■
Definition (`negMap`). The approximable negation map on streams.
Proof. By definition. ■
Theorem (`negMap_strBot`). The named law for stream negation.
Proof. Use the approximable-map presentation of negation. ■
Theorem (`negMap_strElem`). The named law for stream negation.
Proof. Use the approximable-map presentation of negation. ■
Theorem (`d_hcone`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Theorem (`d_hsing`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Definition (`dMap`). The approximable doubling map on streams.
Proof. By definition. ■
Theorem (`dMap_strBot`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Theorem (`dMap_strElem`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Definition (`shape`). The neighbourhood shape for a total/partial flag and a finite prefix.
Proof. By definition. ■
Theorem (`memC_shape`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Definition (`shapeElem`). The principal element of a shape neighbourhood.
Proof. By definition. ■
Theorem (`shapeElem_true`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`shapeElem_false`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Definition (`SLe`). The comparison relation used to merge two shaped streams.
Proof. By definition. ■

Definition (`mergeVal`). The finite merge of two flagged strings.
Proof. By definition. ■
Theorem (`mergeVal_nil`). The named base or successor case.
Proof. By unfolding the definition. ■
Theorem (`mergeVal_cons_nil`). The named base or successor case.
Proof. By unfolding the definition. ■
Theorem (`mergeVal_cons_cons`). The named base or successor case.
Proof. By unfolding the definition. ■
Theorem (`SLe_cons2`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`SLe_cons_inv`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Definition (`mergeElem`). The stream element of a merged pair of shapes.
Proof. By definition. ■
Theorem (`mergeVal_SLe`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`shapeElem_le_iff`). The named comparison or prefix law for stream principals.
Proof. Unpack principal order via cones and singletons. ■
Theorem (`mergeElem_mono`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`shape_injective`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`shape_refine`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Definition (`mergeMap`). The approximable merge of a product of streams.
Proof. By definition. ■
Theorem (`consMap_shapeElem`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`map_ext_C`). The named extensionality or constructor law.
Proof. Compare approximable maps on principals. ■
Theorem (`memC_eq_shape`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`mergeMap_pair`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`mergeVal_diag`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`mergeElem_diag`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`mergeMap_diag`). The named law for merge or shapes.
Proof. Case on the merge/shape definitions. ■
Theorem (`negMap_comp_negMap`). The named law for stream negation.
Proof. Use the approximable-map presentation of negation. ■
Theorem (`negMap_negMap`). The named law for stream negation.
Proof. Use the approximable-map presentation of negation. ■
Theorem (`neg_cons_false`). The named law for stream negation.

Proof. Use the approximable-map presentation of negation. ■

Theorem (`neg_cons_true`). The named law for stream negation.

Proof. Use the approximable-map presentation of negation. ■

Theorem (`prod_principal_pair`). The named law for flip, double, or tail.

Proof. Unfold the string operations and the map laws. ■

Theorem (`prodMap_ext`). The named extensionality or constructor law.

Proof. Compare approximable maps on principals. ■

Theorem (`mergeMap_cons`). The named base or successor case.

Proof. By unfolding the definition. ■

Theorem (`tailMap_consMap_strBot`). The named law for flip, double, or tail.

Proof. Unfold the string operations and the map laws. ■

Theorem (`tailMap_consMap_strElem`). The named law for flip, double, or tail.

Proof. Unfold the string operations and the map laws. ■

Definition (`expand`). The Thue–Morse expansion step on a finite string.

Proof. By definition. ■

Theorem (`expand_nil`). The named base or successor case.

Proof. By unfolding the definition. ■

Theorem (`expand_cons`). The named base or successor case.

Proof. By unfolding the definition. ■

Definition (`tm`). The Thue–Morse bit of a natural number.

Proof. By definition. ■

Definition (`tmOp`). The operator whose fixed point is the Thue–Morse stream.

Proof. By definition. ■

Theorem (`tm_zero`). The named base or successor case.

Proof. By unfolding the definition. ■

Definition (`tmList`). The finite Thue–Morse prefix of a given length.

Proof. By definition. ■

Theorem (`tmList_zero`). The named base or successor case.

Proof. By unfolding the definition. ■

Definition (`tElt`). The Thue–Morse stream element.

Proof. By definition. ■

Theorem (`cone_univ_iff`). The named stream fact.

Proof. Follows from the surrounding stream and fixed-point laws. ■

Theorem (`expand_append`). The named law for the Thue–Morse stream.

Proof. Use the binary-bit and fixed-point characterisations. ■

Theorem (`iterate_expand_cons`). The named base or successor case.

Proof. By unfolding the definition. ■

Theorem (`mergeVal_snd_false`). The named law for merge or shapes.

Proof. Case on the merge/shape definitions. ■

Theorem (`strBot_mem_cone`). The named comparison or prefix law for stream principals.

Proof. Unpack principal order via cones and singletons. ■

Theorem (`strBot_nil`). The named base or successor case.

Proof. By unfolding the definition. ■

Theorem (`tElt_unfold`). The named law for the Thue–Morse stream.

Proof. Use the binary-bit and fixed-point characterisations. ■

Theorem (`tmList_length`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`tmList_succ`). The named base or successor case.
Proof. By unfolding the definition. ■
Theorem (`tmList_prefix`). The named comparison or prefix law for stream principals.
Proof. Unpack principal order via cones and singletons. ■
Theorem (`tmOp_strBot`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`tm_two_mul`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`tm_two_mul_add_one`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`expand_tmList`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`expand_iterate_eq`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`weave_head`). The named stream fact.
Proof. Follows from the surrounding stream and fixed-point laws. ■
Theorem (`tmOp_strBot_expand`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`iterElem_succ_eq`). The named stream fact.
Proof. Follows from the surrounding stream and fixed-point laws. ■
Definition (`Overlap`). A periodic overlap predicate on Thue–Morse bits.
Proof. By definition. ■
Theorem (`append_three_period`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Theorem (`tmList_getElem?`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`tm_of_eq_two_mul`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`tm_of_eq_two_mul_add_one`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`tm_two_mul_ne`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`odd_of_consec_eq`). The named law for flip, double, or tail.
Proof. Unfold the string operations and the map laws. ■
Theorem (`no_three_consec`). The named stream fact.
Proof. Follows from the surrounding stream and fixed-point laws. ■
Theorem (`no_overlap`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`no_cube`). The named law for the Thue–Morse stream.
Proof. Use the binary-bit and fixed-point characterisations. ■
Theorem (`tmList_le_tElt`). The named comparison or prefix law for stream principals.
Proof. Unpack principal order via cones and singletons. ■
Theorem (`tElt_digit`). The named law for the Thue–Morse stream.

Proof. Use the binary-bit and fixed-point characterisations. ■

Theorem (`tElt_mem_cone_iff`). The named law for the Thue–Morse stream.

Proof. Use the binary-bit and fixed-point characterisations. ■

Theorem (`tElt_cube_free`). The named law for the Thue–Morse stream.

Proof. Use the binary-bit and fixed-point characterisations. ■

4.6.36 Exercise 5.16 — negation of sequences

Return to the discussion of Example 4.4 and the construction of the domain of finite and infinite binary sequences. Give a fixed-point definition of $\mathrm{neg} : C \to C$, where

$$\mathrm{neg}(0x) = 1\,\mathrm{neg}(x); \qquad \mathrm{neg}(1x) = 0\,\mathrm{neg}(x).$$

Prove that $\mathrm{neg}(\mathrm{neg}(x)) = x$ for all $x \in |C|$. Also define $\mathrm{merge} : C \times C \to C$, where for $\epsilon, \delta \in \{0, 1\}$ we have:

$$\mathrm{merge}(\epsilon x, \delta y) = \epsilon\,\delta\,\mathrm{merge}(x, y).$$

(Note: There may be a little trouble with $\mathrm{merge}(x, y)$ when x is finite and total and y is infinite—you have to decide what you want in e.g. $\mathrm{merge}(\Lambda, y)$.) Prove that

$$\mathrm{merge}(x, x) = d(x),$$

in the notation of 4.4. Consider also the infinite non-periodic sequence

$$t = 0\,\mathrm{merge}(\mathrm{neg}(t), \mathrm{tail}(t)).$$

Prove that the nth digit of t is the sum mod 2 of the digits of the number n written in the binary scale (a suggestion of J. Lambek). Show also that $t \neq u\,a\,a\,a\,v$ where a is any finite sequence $\neq \Lambda$, and where u is finite.

The development is with the sequence negation and merge peer.

Theorem (`example_516`). Negation is an involution on the stream domain; merge on the diagonal recovers doubling; and no principal of a cube prefix with nonempty period lies below the Thue–Morse stream.

Proof. The involution, diagonal-merge, and cube-freeness laws from the sequence-negation-and-merge peer. ■

Figure 51: Diagram 16

4.7.1 Introduction

The major reason for introducing the theory of domains is to have a notion of *computability* incorporating both finite and infinite elements. In our many examples already explored we have seen how functions (functionals, operators, combinators) can be defined on domains; owing to the property of *approximability (continuity)* of these functions, we have also seen how they can be "calculated" by finite approximation. In this lecture further examples of domains will be constructed – especially domains having infinite elements,

which can be introduced in a variety of ways giving rise to interesting structural possibilities. The next lecture then treats a precise notion of *computability* appropriate to these domains; while the last lecture opens up new methods of domain construction.

4.7.2 Indefinite product

Indefinite product domain: embeddings of atoms and pairs, the generated neighbourhood system, and its characterisation as Scott's D♯.

4.7.3 Example 6.1 — indefinite product

EXAMPLE 6.1. Let D be fixed as a given domain. We are now familiar with a useful construct like $D \times D$ whose elements are ordered pairs $\langle x, y\rangle$ of elements x, y of D. The question is: can this construct be iterated? The answer is obviously yes, since $D \times (D \times D)$ and $(D \times D) \times (D \times D)$ and so on can be formed with elements $\langle x, \langle y, z\rangle\rangle$ and $\langle\langle u, v\rangle, \langle x, y\rangle\rangle$ and the like. But the real question is: can the construct be iterated *indefinitely*? AND can the results be collected together into a *single* domain? The answer is yes, but it requires a bit of work to get it right. The method to be introduced will be open to many variations, so more than one answer is possible, giving non-isomorphic domains.

In order to collect all the iterates into one large domain we give ourselves first a very big domain inside of which the desired family of neighbourhoods will be found. There are many ways to make this choice, and we are fixing on one that will keep the notation simple. We have often used binary sequences for examples and constructions, but for this example let us use

ternary sequences. Let $\Sigma = \{0, 1, 2\}$ and let Σ^* be all finite sequences from this three-letter alphabet. We will select subsets of Σ^* for our neighbourhoods. As Σ^* is countably infinite, it is without much loss of generality to assume that $\mathcal{D}$ is a neighbourhood system over Δ, where we take $\Delta \subseteq \Sigma^*$. Also without loss of generality we can assume $\emptyset \notin \mathcal{D}$. (Why?)

We wish to find another set $\Gamma \subseteq \Sigma^*$ to be the set of tokens for the new domain. After we find it, we will still have to say just which $X \subseteq \Gamma$ are appropriate for the structure we want.

The totality $\{X \mid X \subseteq \Sigma^*\}$ is, as a powerset, isomorphic to the set of elements of a domain: a point we have remarked several times. So, by the Fixed-Point Theorem we know there is a set $\Gamma \subseteq \Sigma^*$ where

$$\Gamma = 0\Delta \cup 1\Gamma \cup 2\Gamma.$$

In fact $\Gamma = \{1, 2\}^*0\Delta$, because we can say:

$$\{1, 2\}^* = \{\Lambda\} \cup 1\{1, 2\}^* \cup 2\{1, 2\}^*.$$

The domain we are looking for will be found as a domain $\mathcal{D}^\S$ over Γ. The reason for splitting Γ up, as shown in the equation above, is to ensure that if $X, Y \in \mathcal{D}^\S$ are two neighbourhoods in the system $\mathcal{D}^\S$, then $1X \cup 2Y$ has a chance of being also in $\mathcal{D}^\S$ because

$$1X \cup 2Y \subseteq \Gamma.$$

This will make $\mathcal{D}^\S \times \mathcal{D}^\S$ isomorphic to a part of $\mathcal{D}^\S$. If we make $\mathcal{D}$ also isomorphic to a part of $\mathcal{D}^\S$, then all the iterated products will be contained in $\mathcal{D}^\S$.

What is a neighbourhood system? Just a set of sets. But $\mathcal{P}\mathcal{P}\Sigma^*$ is a domain (as a power set) and because $\Gamma \subseteq \Sigma^*$, we find

$$\mathcal{D}^\S \in \mathcal{P}\mathcal{P}\Sigma^*$$

as an element. But elements of domains can often be defined by fixed-point equations. Indeed we will introduce $\mathcal{D}^\S$ this way:

$$\mathcal{D}^\S = \{\Gamma\} \cup \{0X \mid X \in \mathcal{D}\} \cup \{1X \cup 2Y \mid X, Y \in \mathcal{D}^\S\}.$$

The reader should stop to think why $\mathcal{D}^\S$ can be immediately seen to exist by writing such an equation. Of course another way to describe $\mathcal{D}^\S$ is to say it is the least family of sets containing (i) the set Γ, (ii) the sets $0X$ for X in the given system $\mathcal{D}$, and (iii) sets $1X \cup 2Y$ whenever it already contains X and Y (closure

under a set-forming operation). By saying "least" we mean (iv) nothing else belongs to $\mathcal{D}^\S$ except as allowed by (i)–(iii); this makes the truth of the equation for $\mathcal{D}^\S$ clear. So $\mathcal{D}^\S$ exists as a family of sets, but what good is it?

By our construction of Γ, all the sets we put into $\mathcal{D}^\S$ are subsets of Γ (why?); so $\mathcal{D}^\S$ has a chance of being a system over Γ if we can check the closure under intersection. So suppose $Z \subseteq X \cap Y$ where $Z, X, Y \in \mathcal{D}^\S$; we want to show $X \cap Y \in \mathcal{D}^\S$. We argue by induction on the number of steps required to put X and Y into $\mathcal{D}^\S$ by (i)–(iii). There are several cases.

If $X = \Gamma$ or $Y = \Gamma$, there is nothing to prove, because both sets are subsets of Γ. We note that $\emptyset \notin \mathcal{D}^\S$, because (i)–(iii) cannot introduce $\emptyset$ as a member of $\mathcal{D}^\S$. So, if $X = 0A$ for $A \in \mathcal{D}$, then Y must have this form also (if it is not Γ), because

$$0A \cap (1B \cup 2C) = \emptyset.$$

(That is, if Y had the form (iii), then $Z = \emptyset$ would be a consequence, which is impossible.) Thus, if $X = 0A$ for $A \in \mathcal{D}$, then $Y = 0B$ for some $B \in \mathcal{D}$. But by the same reasoning $Z = 0C$ for some $C \in \mathcal{D}$ also. But the relationship $0C \subseteq 0A \cap 0B$ is equivalent to $C \subseteq A \cap B$. We see, therefore, that $A \cap B \in \mathcal{D}$, and so

$$X \cap Y = 0A \cap 0B = 0(A \cap B)$$

must belong to $\mathcal{D}^\S$.

The final case has X, Y, Z all of the form (iii):

$$X = 1A_1 \cup 2A_2,$$

$$Y = 1B_1 \cup 2B_2, \text{ and}$$

$$Z = 1C_1 \cup 2C_2.$$

We can think of the A_i and B_i put into $\mathcal{D}^\S$ earlier and the intersection result as being already established for them. But the relationship $Z \subseteq X \cap Y$ is equivalent to $C_i \subseteq A_i \cap B_i$ for $i = 1, 2$. Therefore $A_i \cap B_i \in \mathcal{D}^\S$, and so does

$$X \cap Y = (1A_1 \cup 2A_2) \cap (1B_1 \cup 2B_2) = 1(A_1 \cap B_1) \cup 2(A_2 \cap B_2).$$

We have now seen that $D^\S$ is a neighbourhood system, but why was it constructed that way? The reason is simply this isomorphism (or domain equation):

$$D^\S \cong D + (D^\S \times D^\S),$$

as can be seen by reference to the equation for $D^\S$ and the definitions of $+$ and $\times$. What are the elements of $D^\S$? There is always

$$\perp = \{\Gamma\}.$$

Next if $x \in |D|$ we define

$$x^\S = \{\Gamma\} \cup \{0X \mid X \in x\}.$$

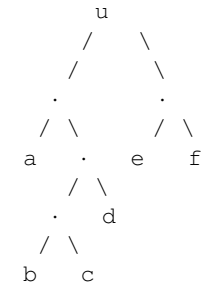
That gives an isomorphic injection

$$\lambda x.\, x^{\S} : D \to D^{\S}.$$

Then for $x, y \in |D^{\S}|$ we can define

$$\langle x, y\rangle = \{\Gamma\} \cup \{1X \cup 2Y \mid X \in x \text{ and } Y \in y\}.$$

We have another isomorphic injection



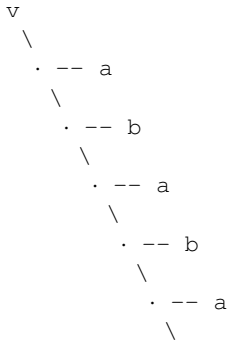
$$\lambda x, y.\, \langle x, y\rangle : D^{\S} \times D^{\S} \to D^{\S}.$$

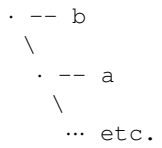
Indeed by looking at the neighbourhood definition of $D^{\S}$ we conclude that the *finite* elements of $D^{\S}$ are exactly those that are either of the form (i) $\bot$, or (ii) $a^{\S}$, where a is finite in $|D|$, or (iii) $\langle a, b\rangle$, where a and b are previously obtained finite elements of $|D^{\S}|$.

Suppose $a, \ldots, f$ are finite in $|D|$. We can picture the element

$$u = \langle\langle a^{\S}, \langle\langle b^{\S}, c^{\S}\rangle, d^{\S}\rangle\rangle, \langle e^{\S}, f^{\S}\rangle\rangle$$

in $|D^{\S}|$ as a tree:





Note that the tree has binary branching with the elements of $|D|$ at the ends of the branches. Any such tree could be given a notation as an element of $|D^{\S}|$. The finite elements of $|D^{\S}|$ correspond exactly to such finite trees.

What of the infinite elements of $|D^{\S}|$? Are there infinite trees? Let $a, b \in |D^{\S}|$ be any elements of $|D^{\S}|$. Since pairing is an approximable mapping, we can solve the fixed-point equation

$$v = \langle a, \langle b, v\rangle\rangle.$$

In pictures we can diagram v roughly as:

The word is "roughly" here, since if a or b were not in the $|D|$ part of $|D^{\S}|$, then in the diagram the letters "a" and "b" should be replaced by the corresponding tree diagrams for a and b.

Suppose that a and b are finite. Then we can easily see that the infinite tree v is the limit of the following sequence of finite trees:

$$v_0 = \bot,$$

$$v_{n+1} = \langle a, \langle b, v_n \rangle \rangle,$$

and

$$v = \bigcup_{n=0}^{\infty} v_n.$$

The reader should think how to explain from tree diagrams the approximation relation $v_n \sqsubseteq v$ and more general such relationships.

We could call $D^{\S}$ a tree algebra over D. There may be others. A general one is a structure of the form

$$\langle E, \text{in}, \text{pair} \rangle,$$

where

$$\text{in} : D \to E, \text{ and}$$

$$\text{pair} : E \times E \to E.$$

The algebra

$$\langle D^{\S}, \lambda x.\, x^{\S}, \lambda x, y.\, \langle x, y \rangle \rangle,$$

however, is a very special one: it is "minimal" among all tree algebras over D in a sense we shall have to make precise.

To do this think of how E and $D^{\S}$ can differ. In view of the isomorphism that $D^{\S}$ satisfies, the injection of D and the pairing are one-one, so no "information" is lost by these mappings. The same may not at all be true of E, but it is reasonable to think that at least we can define an approximable mapping $g : D^{\S} \to E$ where

$$(1) \quad g(\bot) = \bot_E,$$

$$(2) \quad g(x^{\S}) = \text{in}(x), \text{ for } x \in |D|, \text{ and}$$

$$(3) \quad g(\langle x, y \rangle) = \text{pair}(g(x), g(y)), \text{ for } x, y \in |D^{\S}|.$$

By what we said earlier, g will be uniquely determined by (1)–(3), because these equations tell us exactly how to calculate g on all finite elements of $|D^{\S}|$. An approximable mapping is always determined by its action on the finite elements. But why does g exist?

It would not be too hard to give an inductive construction of g as a neighbourhood relation, but a fixed-point equation is easier to write down for the same purpose. We need, though, to have the inverse ("predecessor") functions:

$$\text{out} : D^{\S} \to D$$

$$\text{proj}_i : D^{\S} \to D^{\S}, \text{ for } i = 0, 1,$$

where

$$\text{out}(x^{\S}) = x,$$

$$\text{proj}_0(\langle x, y\rangle) = x, \text{ and}$$

$$\text{proj}_1(\langle x, y\rangle) = y.$$

We also need

$$\text{atom} : D^{\S} \to T,$$

where

$$\text{atom}(x^{\S}) = \text{true}, \text{ and}$$

$$\text{atom}(\langle x, y\rangle) = \text{false}.$$

We can then write

$$g(x) = \text{cond}\big(\text{atom}(x),\ \text{in}(\text{out}(x)),\ \text{pair}(g(\text{proj}_0(x)),\ g(\text{proj}_1(x)))\big).$$

This g exists by fixed-point theory, and it satisfies (1)–(3) by what we know about the structure of $|D^{\S}|$. As we said, g is unique because the values on finite elements are fixed.

In algebraic language g is a *homomorphism* of tree algebras; and $D^{\S}$ is called an *initial algebra*, because for any tree algebra E there is a unique homomorphism $g : D^{\S} \to E$. We note at once that any two initial algebras are isomorphic. For if D^* were another, there would exist homomorphisms in both directions between $D^{\S}$ and D^*. But the compositions of homomorphisms are again homomorphisms, and in the case of $D^{\S}$ if we go from $D^{\S}$ to D^* and back to $D^{\S}$, the result must be the identity. The reason is that the identity can be the only homomorphism of an initial algebra into itself. We thus have a precise meaning of the minimal character of $D^{\S}$. But note it still took a construction to show that the domain $D^{\S}$ exists. □

The development is with the indefinite product peer.

Theorem (`example_61`). For a neighbourhood system whose neighbourhoods are nonempty, the indefinite product is a neighbourhood system whose membership is the MemS inductive family and whose master is the Gamma set of tagged master tokens.

Proof. The membership and master characterisations of the indefinite-product peer. ■

4.7.8 Example 6.2 — sequence domain equations

EXAMPLE 6.2. Our staple examples B and C satisfy "domain equations" in the form of isomorphisms as we have previously seen. Indeed

$$B \cong B + B, \text{ and}$$

$$C \cong \{\{\Lambda\}\} + C + C,$$

where if we liked we could construct both systems over $\{0,1\}^*$ and have:

$$B = \{\{0,1\}^*\} \cup \{0X \mid X \in B\} \cup \{1X \mid X \in B\}, \text{ and}$$

$$C = \{\{0,1\}^*\} \cup \{\{\Lambda\}\} \cup \{0X \mid X \in C\} \cup \{1X \mid X \in C\}.$$

We leave to the exercises the explanations of what kinds of algebras B and C are and why they are initial. Here we want to propose a simple, yet interesting generalization of B.

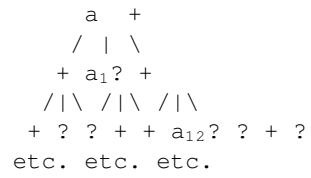
Consider this domain equation:

$$A \cong A^n + A^n,$$

where A^n stands for the n-fold cartesian power of A. We can, with the aid of some encoding solve this equation as a neighbourhood system over $\{0,1\}^*$ as follows:

$$A = \{\{0,1\}^*\} \cup \bigcup_{i=0,1} \left\{ i \bigcup_{j<n} 1^j 0 X_j \mid X_j \in A \text{ for all } j < n \right\}.$$

For instance, if $n = 3$, then a typical neighbourhood in A is something like



$$00X_0 \cup 010X_1 \cup 0110X_2,$$

where $X_0, X_1, X_2 \in A$. The first '0' could also be a '1' in front of each of the terms.

In words, an element of A (other than $\perp$) is an n-tuple of elements of A: but there are two separate copies of these, the left one and the right one. We can write for $a \in |A|$

$$a = \pm\langle a_0, a_1, \ldots, a_{n-1}\rangle,$$

where $+$ is chosen if a is on the right, and $-$ if on the left. As a tree diagram a might look like this for $n = 3$:

That is, a is an infinite ternary tree with $+$ or $-$ labels at each node. If each node (subtree) is truly infinite, the element is *total*; if $\perp$ is ever encountered, it is only *partial*; if every branch ends with $\perp$, the tree is a *finite element* of $|A|$.

What can be done with such trees? Let $\sigma \in \{0,1,\ldots,n-1\}^*$ be a finite sequence of "digits" each less than n. We let $\Sigma = \{0,1,\ldots,n-1\}$. We can define for $a \in |A|$ the operation $\sigma \mapsto a\sigma$ by recursion on σ:

$$a\Lambda = a, \text{ and}$$

$$ai\sigma = (a_i)\sigma.$$

The $a\sigma$ are just the *subtrees* of a with σ as a *selector*. We also have a map

$$\text{pos} : A \to T$$

where

$$\text{pos}(+\langle a_0, a_1, \ldots, a_{n-1}\rangle) = \text{true}, \text{ and}$$

$$\mathrm{pos}(-\langle a_0, a_1, \ldots, a_{n-1}\rangle) = \mathrm{false}.$$

We say that a (total) tree a is *eventually periodic* iff the set $\{a\sigma \mid \sigma \in \Sigma^*\}$ is finite. The result is that the "language"

$$L_a = \{\sigma \in \Sigma^* \mid \mathrm{pos}(a\sigma) = \mathrm{true}\}$$

corresponding to an eventually periodic tree is always a *regular event* of automata theory, and every such language has this form. In fact, a just represents the initial state of an automaton, and $a\sigma$ represents the state after "reading" a tape σ. □

Theorem (`example_62`). Scott's Example 6.2: the domains B and C satisfy their domain equations; for positive n the system A^n satisfies A^n ≅ A^n + A^n; and languages over Fin n are regular exactly when they arise from eventually periodic selector trees.

Proof. Combine B_domain_equation, C_domain_equation, A_domain_equation, and isRegular_iff_exists_eventuallyPeriodic from the companion libraries. ■

```

4.7.10 Definition 6.3 — functor

DEFINITION 6.3. A *functor* on a category (into itself) associates with every domain X in the category another domain $T(X)$ and to every map

$$f : X \to Y$$

another map

$$T(f) : T(X) \to T(Y)$$

in such a way that identity maps and compositions are preserved:

$$T(I_X) = I_{T(X)}, \text{ and}$$

$$T(g \circ f) = T(g) \circ T(f),$$

whenever $f : X \to Y$ and $g : Y \to Z$. □

In the example from 6.1 we have not checked how the special **T** is a functor. The hint is that whenever $f : X \to Y$, then there is a map

$$f \times f : X \times X \to Y \times Y.$$

But there is also a map

$$I_D + f \times f : D + (X \times X) \to D + (Y \times Y)$$

and this suggests the definition of $T(f)$. The details are left to the exercises. Note that the map $T(f)$ just suggested is always strict, so **T** is a functor also for the category of strict maps.

One good reason for a little of the category-theoretic language is that the next definition becomes very neat indeed.

The endofunctor peer records the library names.

Theorem (`definition_63`). For each endofunctor, identity morphisms and composition are preserved under the object and morphism actions.

Proof. The packaged equalities are exactly the endofunctor axioms. ■

  comm : hom ? A.str = B.str ? T.map hom

end DomainTheory.NeighbourhoodSystems
```

4.7.12 Definition 6.4 — algebra for a functor

DEFINITION 6.4. A ***T*-algebra** is a domain E in the category together with a map

$$k : T(E) \to E.$$

If $m : T(F) \to F$ is another ***T*-algebra**, then a *homomorphism* is a map $h : E \to F$ in the category such that the diagram

$$\begin{array}{ccc} T(E) & \xrightarrow{k} & E \\ \downarrow{\scriptstyle T(h)} & & \downarrow{\scriptstyle h} \\ T(F) & \xrightarrow{m} & F \end{array}$$

commutes; that is, the equation

$$h \circ k = m \circ T(h)$$

holds. □

In our example from 6.1 a T-algebra is a *strict* map

$$k : D + (E \times E) \to E.$$

But such strict maps are in a one-one correspondence with pairs of (not necessarily strict) maps

$$n : D \to E \quad \text{and} \quad p : E \times E \to E.$$

And the structure $\langle E, n, p \rangle$ is what we called a tree algebra. Definition 6.4 just makes this abstract. The reader should also work out the details showing that 6.4's definition of homomorphism is just what we ought to expect.

Note that the T-algebras and homomorphisms form a category. (Why?) The following definition is so abstract that it could be given for any category.

The T-algebra peer records the library names.

Theorem (`definition_64`). Every algebra homomorphism satisfies the commuting-square equation.

Proof. This is the defining commutativity field of an algebra homomorphism. ■

4.7.13 Initial algebra

Initial T-algebras, the category of homomorphisms, and the identity endofunctor (Def 6.5 library).

Definition (`IsInitial`). A T-algebra is initial when it has a chosen homomorphism into every algebra and that homomorphism is unique.

Proof. By definition. ■

Definition (`AlgHom.comp`). Composition of algebra homomorphisms is composition of the underlying morphisms, with the commutativity law inherited from functoriality and the squares for the factors.

Proof. Apply associativity, the commutative squares, and preservation of composition by the functor. ■

Definition (`AlgHom.id`). The identity morphism on the carrier is an algebra homomorphism.

Proof. Uses identity laws and the functor's preservation of identity. ■

Theorem (`AlgHom.id_hom`). The underlying morphism of the identity homomorphism is the identity on the carrier.

Proof. By definition. ■

Theorem (`AlgHom.comp_hom`). The underlying morphism of a composite homomorphism is the composite of the underlying morphisms.

Proof. By definition. ■

Definition (`idEndofunctor`). The identity endofunctor fixes objects and morphisms.

Proof. By definition. ■

Theorem (`idEndofunctor_obj`). The identity endofunctor leaves each object unchanged.

Proof. By definition. ■

Theorem (`idEndofunctor_map`). The identity endofunctor leaves each morphism unchanged.

Proof. By definition. ■

4.7.14 Definition 6.5 — initial algebra

DEFINITION 6.5. A T-algebra is *initial* if and only if there is a unique homomorphism from it into any other T-algebra. □

The word "other" here is not meant to imply "distinct". For an initial algebra there is one and only one homomorphism into itself: the identity map. As we already indicated in 6.1 it is a general fact that the next proposition holds.

The initial algebra peer records the library names and the homomorphism category.

Theorem (`definition_65`). An initial algebra has a homomorphism into every algebra, and any two such homomorphisms agree.

Proof. By the description and uniqueness fields packaged with initiality. ■

`Definition_6_5.lean`

```
module

public import DomainTheory.NeighbourhoodSystems.DomainEquations.initialAlgebra

end DomainTheory.NeighbourhoodSystems
```

4.7.15 Initial iso

Uniqueness and isomorphism of initial algebras (Proposition 6.6 library).

Theorem (`comp_desc_eq_id`). Composing the two canonical homomorphisms between initial algebras in opposite directions yields the identity.

Proof. Both composites and the identity are homomorphisms into an initial algebra; uniqueness forces agreement. ■

Definition (`initialIso`). For initial algebras, the forward and backward canonical homomorphisms assemble an isomorphism of carriers.

Proof. The inverse laws reduce to the round-trip identities from the previous lemma. ■

Theorem (`iso_hom_unique`). Every homomorphism from an initial algebra equals the canonical one.

Proof. By initiality. ■

4.7.16 Proposition 6.6 — uniqueness of initial algebras

PROPOSITION 6.6. Any two initial T-algebras are uniquely isomorphic. □

Slightly more interesting is the behaviour of T on initial algebras.

The initial iso peer records the library names for the isomorphism and uniqueness lemmas.

Theorem (`proposition_66`). Every homomorphism from an initial algebra agrees with the canonical homomorphism furnished by initiality.

Proof. Invoke uniqueness of homomorphisms from an initial algebra. ■

4.7.17 Lambek

Lambek's lemma: the structure map of an initial algebra is an isomorphism (Proposition 6.7 library).

Definition (`tStr`). Applying the functor to an algebra yields the algebra with carrier and structure map given by functorial action.

Proof. By definition. ■

Definition (`strHom`). The structure map is a homomorphism from the algebra obtained by functorial rearrangement.

Proof. The commutativity square holds by reflexivity. ■

Theorem (`str_comp_desc`). Composing the structure map with the canonical descent homomorphism yields the identity on the carrier.

Proof. Both sides are homomorphisms into an initial algebra; uniqueness identifies them. ■

Definition (`lambek`). The structure map and its descent inverse form an isomorphism between the functor image of the carrier and the carrier itself.

Proof. One inverse law is the preceding theorem; the other uses the homomorphism square and functoriality. ■

4.7.18 Proposition 6.7 — functor preserves initiality

PROPOSITION 6.7. If $i : T(D) \to D$ is an initial T-algebra, then so is $T(i) : T^2(D) \to T(D)$ and i is the isomorphism from $T(D)$ to D.

Proof: Clearly since T is a functor, the map $T(i)$ has the right mapping character to make $T(D)$ a T-algebra. Since D is initial, we have a commuting diagram:

$$\begin{array}{ccc} T(D) & \xrightarrow{i} & D \\ \downarrow{\scriptstyle T(j)} & & \downarrow{\scriptstyle j} \\ T^2(D) & \xrightarrow{T(i)} & T(D) \end{array}$$

But we also have the trivial diagram:

$$\begin{array}{ccc} T^2(D) & \xrightarrow{T(i)} & T(D) \\ \downarrow{\scriptstyle T(i)} & & \downarrow{\scriptstyle i} \\ T(D) & \xrightarrow{i} & D \end{array}$$

It follows that $i \circ j$ is a homomorphism, so

$$i \circ j = I_D.$$

But then because T is a functor we find:

$$T(i) \circ T(j) = I_{T(D)},$$

and, since j is a homomorphism, we have

$$j \circ i = I_{T(D)}.$$

This shows that i is an isomorphism. □

From 6.7 we see that if we are going to have initial algebras at all we have to satisfy the domain equation

$$D \cong T(D).$$

But generally that is not enough to assure that D is initial. There is a condition that our functors satisfy, however, which guarantees the existence of homomorphisms.

The Lambek peer records the library names for the isomorphism and its auxiliary maps.

Theorem (`proposition_67`). For an initial algebra, the structure map followed by the canonical descent homomorphism is the identity on the carrier.

Proof. Apply the round-trip identity packaged with the peer library. ■

4.7.20 Definition 6.8 — continuity on maps

DEFINITION 6.8. On the category of domains and strict approximable maps a functor T is *continuous on maps* if for any systems D and E the induced mapping

$$\lambda f.\, T(f) : (D \to_\perp E) \to (T(D) \to_\perp T(E))$$

is approximable.

The continuous on maps peer records the library names.

Theorem (`definition_68`). A functor is continuous on maps exactly when, for all domains D and E, the induced map on strict approximable functions is approximable with action $T(f)$.

Proof. This is the definition packaged as a biconditional. ■

Definition_6_8.lean

```

4.7.21 Initial homomorphism

Theorem 6.9 library: post/pre-composition on strict function spaces and existence of algebra homomorphisms.

Definition (`homOpComp`, `homOp`). For strict post- and pre-composition with domain maps, the operator $g \mapsto k \circ g \circ j$ is an approximable self-map of the strict function space.

Proof. Built by monotonic extension from its action on principal neighbourhoods. ■

Theorem (`homOp_apply_filter`). The approximable operator realizes strict post/pre-composition on filters of strict maps.

Proof. By comparison on single-step neighbourhoods through the strict function-space representation. ■

Theorem (`nonempty_algHom_of_continuousOnMaps`). If T is continuous on maps and $D \cong T(D)$, then every strict T-algebra admits a strict homomorphism from D.

Proof. The homomorphism equation is a fixed-point equation for an approximable operator; a least fixed point yields the desired homomorphism. ■

4.7.22 Theorem 6.9 — homomorphism from initial algebra

THEOREM 6.9. If the functor T is continuous on maps and if $D \cong T(D)$, so in particular D is a T-algebra, then for any T-algebra $k : T(E) \to E$ there is a homomorphism $h : D \to E$.

Proof: Let $i : T(D) \to D$ make D a T-algebra, where $j : D \to T(D)$ is the inverse so that i is an isomorphism of domains. Suppose that $k : T(E) \to E$ is any T-algebra. A homomorphism $h : D \to E$ would satisfy

$$h \circ i = k \circ T(h).$$

Rewrite this equation as

$$h = k \circ T(h) \circ j.$$

In the domain of strict maps $(D \to E)$ this is a fixed-point equation for an approximable map

$$\lambda h.\, k \circ T(h) \circ j$$

by our assumption on T. Thus, the desired homomorphism exists. □

The initial homomorphism peer records the library development and existence proof.

Theorem (`theorem_69`). Under continuity on maps and $D \cong T(D)$, every strict T-algebra receives a strict homomorphism from D.

Proof. By the fixed-point construction in the initial-homomorphism library. ■

The final question we have to answer is why in our category the minimal D exist. The reason is that the functors T that we have in mind possess further continuity properties on domains. This is conveniently expressed in terms of a notion of "subdomain".

4.7.23 Subdomain

Definition 6.10 library: the subdomain relation $\triangleleft$ on neighbourhood systems over a common token set.

Definition (`Subsystem`). $D \triangleleft E$ means D and E share the same master set, every neighbourhood of D belongs to E, and whenever $X, Y \in D$ with $X \cap Y \in E$, then $X \cap Y \in D$.

Proof. This is the intended mathematical content of Scott's clause (ii) together with $D \subseteq E$. ■

Definition (`?`). Infix notation for the subdomain proposition `Subsystem D E`.

Proof. Notation only. ■

Theorem (`NeighborhoodSystem.ext`). Two systems agreeing on membership and master are equal.

Proof. Extensionality on the membership field and the master token. ■

Theorem (`Subsystem.antisymm`). Mutual subdomain forces equality of systems.

Proof. Compare memberships via each inclusion map and identify masters. ■

Theorem (`Subsystem.refl`). Every system is a subdomain of itself.

Proof. Reflexivity of inclusion and intersection closure. ■

Theorem (`Subsystem.trans`). Subdomain is transitive.

Proof. Chain master equalities and neighbourhood inclusions; intersection closure passes along the chain. ■

Theorem (`Subsystem.subsystem_iff_subset_of_common`). For two subdomains of a common superdomain, subdomain order coincides with neighbourhood inclusion.

Proof. One direction is the subdomain map; the converse builds the intersection-closure clause from shared context. ■

4.7.24 Definition 6.10 — subdomain

DEFINITION 6.10. For two neighbourhood systems D and E we write

$$D \triangleleft E$$

to mean that these are neighbourhood systems over the same set of tokens Δ and not only is $D \subseteq E$ but whenever $X, Y \in D$ and $X \cap Y \in E$, then $X \cap Y \in D$. $\square$

For the subdomain relation $D \triangleleft E$ to hold, D has to be a smaller family of neighbourhoods, but the notion of consistency in D also has to be the same as in E. Note that if $D_0 \triangleleft E$ and $D_1 \triangleleft E$ then

$$D_0 \triangleleft D_1 \text{ iff } D_0 \subseteq D_1.$$

It is also easy to prove that the union of a directed family of subdomains of E is again a subdomain. As a consequence of this remark we have:

The subdomain peer records the library names.

Theorem (`definition_610`). The subdomain relation is equivalent to equality of masters, inclusion of neighbourhood families, and inheritance of consistency for intersections admitted by the superdomain.

Proof. Unfold the subdomain structure in both directions. ■

4.7.25 Subsystem lattice

Proposition 6.11 library: subsystems of a fixed neighbourhood system form a domain.

Definition (`subFam`). Families of neighbourhoods arising as $\{X \mid D.\mathrm{mem}\, X\}$ for some $D \triangleleft E$.

Proof. Definition from the subdomain/data pairing. ■

Theorem (`subFam_inter_closed`). Members of `subFam` are closed under intersections consistent in E.

Proof. Apply the subdomain intersection clause of the witness system. ■

Theorem (`subFam_master_mem`). Every member of `subFam` contains the master neighbourhood of E.

Proof. Master membership in the witness system, rewound along master equality. ■

Theorem (`subFam_mem_E`). Neighbourhoods in a member of `subFam` lie in E.

Proof. Subdomain inclusion from the witness. ■

Definition (`interSys`). System whose neighbourhoods lie in every family of a nonempty family from `subFam`.

Proof. Pointwise intersection membership defines a neighbourhood system over E's tokens. ■

Theorem (`interSys_nbset`). The neighbourhood family of `interSys` is the set-theoretic intersection of the family.

Proof. Characterization of membership in a global intersection. ■

Theorem (`interSys_subsystem`). `interSys` is a subdomain of E.

Proof. Master fixed to E; inclusion and intersection inheritance from `subFam` lemmas. ■

Definition (`ofMem`). Rebuild a neighbourhood system from a family in `subFam`.

Proof. Membership is literal membership in the family; axioms from `subFam` closure. ■

Theorem (`ofMem_subsystem`). `ofMem` recovers a subdomain of E.

Proof. Reflexivity of the data packaged with `subFam` membership. ■

Definition (`subPartialOrder`). Subsystems of E ordered by subdomain.

Proof. Reflexivity, transitivity, and antisymmetry from subdomain lemmas. ■

Theorem (`subFam_nonempty`). `subFam E` is nonempty.

Proof. The full family $\{X \mid E.\mathrm{mem}\, X\}$ arises from E itself. ■

Theorem (`subFam_sInter_mem`). Nonempty families in `subFam` have their intersection in `subFam`.

Proof. Realize the intersection as `interSys`. ■

Definition (`subIso`). Order isomorphism between subsystems of E and families in `subFam`.

Proof. Forward and backward maps are $\{X \mid D.\mathrm{mem}\, X\}$ and ofMem; order preserved by Scott's subset remark. ■

Definition (`unionSys`). System whose neighbourhoods appear in some member of a directed subfamily.

Proof. Existential membership over the directed family; intersection uses directedness. ■

Theorem (`unionSys_nbset`). Neighbourhood family equals the set-theoretic directed union.

Proof. Membership reformulation of $\bigcup$`0`. ■

Theorem (`unionSys_subsystem`). Directed unions of subdomains yield a subdomain.

Proof. Scott's remark realized via `unionSys`. ■

Theorem (`subFam_sUnion_mem`). Directed unions of families in `subFam` remain in `subFam`.

Proof. Witness `unionSys` and its subdomain law. ■

Definition (`subsystemReprIso`). Subsystems of E are order-isomorphic to the representable domain built from `subFam E`.

Proof. Compose `subIso` with the representation isomorphism of Exercise 2.22 using intersection and union closure. ■

4.7.26 Proposition 6.11 — lattice of subsystems

PROPOSITION 6.11. For a given neighbourhood system E, the set of subsystems

$$\{D \mid D \triangleleft E\}$$

forms a domain in its own right. □

The subdomain relationship implies a mapping relationship between the domains.

The subsystem lattice peer records the library names.

Theorem (`proposition_611`). For each E, the subtype of subsystems ordered by $\triangleleft$ is nonempty-order-isomorphic to the domain element type given by the abstract representation of `subFam E`.

Proof. Exhibit `subsystemReprIso`. ■

`Proposition_6_11.lean`

4.7.27 Projection pair library

Proposition 6.12 library: injection and projection maps for a subdomain.

Definition (`ProjectionPair`). A pair of approximable maps with $j \circ i = I_D$ and $i \circ j \subseteq I_E$.

Proof. Structure recording the laws. ■

Definition (`Subsystem.inj`). Relation $X\, i\, Y \leftrightarrow X \in D \wedge Y \in E \wedge X \subseteq Y$.

Proof. Standard approximable-map axioms; intersection uses subdomain inclusion into E. ■

Theorem (`Subsystem.inj_rel`). Unfolding lemma for the injection relation.

Proof. Definition. ■

Definition (`Subsystem.proj`). Relation $Y\, j\, X \leftrightarrow Y \in E \wedge X \in D \wedge Y \subseteq X$; intersection output uses subdomain consistency.

Proof. Approximable-map axioms with `inter_closed` on D. ■

Theorem (`Subsystem.proj_rel`). Unfolding lemma for the projection relation.

Proof. Definition. ■

Theorem (`Subsystem.inj_comp_proj_le`). $i \circ j \subseteq I_E$.

Proof. A round trip through a common D-neighbourhood refines $Y \subseteq Y'$ on E. ■

Theorem (`Subsystem.proj_comp_inj`). $j \circ i = I_D$.

Proof. Relational extensionality; round trips collapse to $\subseteq$ on D. ■

Definition (`Subsystem.projectionPair`). Bundle the maps and laws for $D \triangleleft E$.

Proof. Fields filled from `inj`, `proj`, and the two composition laws. ■

4.7.28 Proposition 6.12 — projection pair

PROPOSITION 6.12. If $D \triangleleft E$, then there exists a projection pair of approximable mappings:

$$i : D \to E \quad \text{and} \quad j : E \to D$$

where $j \circ i = I_D$ and $i \circ j \subseteq I_E$, which are determined as element-wise functions by these equations:

$$i(x) = \{Y \in E \mid \exists X \in x.\, X \subseteq Y\},$$

and

$$j(y) = y \cap D,$$

for all $x \in |D|$ and $y \in |E|$. □

The proof is left for the exercises.

The projection pair library peer records the library names.

Theorem (`proposition_612`). For every subdomain $h : D \triangleleft E$, the standard injection and projection satisfy $i \circ j \subseteq I_E$ and $j \circ i = I_D$.

Proof. Both clauses are the peer composition laws. ■

Theorem (`Subsystem.trianglelefteq`). A subdomain yields the embedding $D \trianglelefteq E$ using D itself as witness.

Proof. Reflexivity of domain isomorphism on the subtype. ■

DEFINITION 6.13. A functor T is *monotone on domains* iff whenever $D \triangleleft E$, then not only do we have $T(D) \triangleleft T(E)$ but the projection pair i, j of 6.12 is mapped to the same kind of projection pair $T(i), T(j)$. A monotone functor is *continuous on domains* iff whenever E is a domain, then the mapping

$$\lambda D.\, T(D) : \{D \mid D \triangleleft E\} \to \{D' \mid D' \triangleleft T(E)\}$$

is approximable. □

We can now state an existence theorem that covers in fairly wide generality the examples of this lecture.

```

THEOREM 6.14. If the functor T is continuous on maps and monotone and continuous on domains, and if there is a set Γ such that

$$\{\Gamma\} \triangleleft T(\{\Gamma\}),$$

then there exists an initial T-algebra.

Proof: We proceed as in the proof of the fixed-point theorem by iterating the functor. The assumption about Γ means that, as a neighbourhood system, $T(\{\Gamma\})$ is a system over the same set Γ. Thus, if we iterate T to form $T^n(\{\Gamma\})$, all these systems are over Γ and indeed

$$T^n(\{\Gamma\}) \triangleleft T^{n+1}(\{\Gamma\})$$

for all n. We can thus introduce

$$\mathcal{D} = \bigcup_{n=0}^{\infty} T^n(\{\Gamma\}),$$

and it is easy to check that $\mathcal{D}$ is a system over Γ and

$$T^n(\{\Gamma\}) \lhd \mathcal{D}$$

holds for all n. But then we have for all n:

$$T^n(\{\Gamma\}) \lhd T^{n+1}(\{\Gamma\}) \lhd T(\mathcal{D}),$$

which implies $\mathcal{D} \lhd T(\mathcal{D})$. But T is continuous on domains, so

$$\begin{aligned} T(\mathcal{D}) &= T\left(\bigcup_{n=0}^{\infty} T^n(\{\Gamma\})\right) \\ &= \bigcup_{n=0}^{\infty} T^{n+1}(\{\Gamma\}) \\ &= \mathcal{D}. \end{aligned}$$

Thus, not only is $\mathcal{D}$ a T-algebra, but the isomorphism we get for $\mathcal{D}$ and $T(\mathcal{D})$ is just the identity mapping. We know by 6.9 that homomorphisms exist; what remains to show is that homomorphism from $\mathcal{D}$ are unique. As in the examples, we will show in effect they are determined uniquely on the finite elements of $\mathcal{D}$.

Since each $T^n(\{\Gamma\}) \lhd \mathcal{D}$, there are projection mappings $i_n : T^n(\{\Gamma\}) \to \mathcal{D}$ and $j_n : \mathcal{D} \to T^n(\{\Gamma\})$.

Define $\rho_n : \mathcal{D} \to \mathcal{D}$ by $\rho_n = i_n \circ j_n$. Projection pairs are always pairs of strict mappings (Why?), and so are in the category. By assumption and 6.13, the functor T preserves these maps, so we have

$$T(\rho_n) = T(i_n) \circ T(j_n) = i_{n+1} \circ j_{n+1} = \rho_{n+1}.$$

As a neighbourhood relation ρ_n can be characterized by :

$$X \rho_n Y \quad \text{iff} \quad \exists z \in T^n(\{\Gamma\}).\ X \subseteq z \subseteq Y.$$

We thus see that $\rho_n \subseteq \rho_{n+1}$ and

$$\bigcup_{n=0}^{\infty} \rho_n = I_{\mathcal{D}}.$$

Now suppose $k : T(E) \to E$ is any T-algebra and $h : \mathcal{D} \to E$ is a homomorphism. The mapping will satisfy the fixed-point equation

$$h = k \circ T(h),$$

where no other mappings need be written in because $\mathcal{D} = T(\mathcal{D})$ and so

$$T(h) : \mathcal{D} \to T(E).$$

We wish to show that h really is the least fixed point of this equation.

Define $h_n = h \circ \rho_n : \mathcal{D} \to E$. For $n = 0$, the map ρ_0 is the trivial map where $\rho_0(x) = \bot_{\mathcal{D}}$ for all $x \in |\mathcal{D}|$. But h must be strict, so $h_0(x) = \bot_E$ for all $x \in |\mathcal{D}|$; that is, h_0 is the least element of $|\mathcal{D} \to_\bot E|$. Now calculate :

$$\begin{aligned} k \circ T(h_n) &= k \circ T(h) \circ T(\rho_n) \\ &= h \circ \rho_{n+1} \\ &= h_{n+1} \,. \end{aligned}$$

This shows that the union of the h_n is the least fixed point of $\lambda h.\, k \circ T(h)$. But

$$\begin{aligned} \bigcup_{n=0}^{\infty} h_n &= \bigcup_{n=0}^{\infty} h \circ \rho_n \\ &= h \circ \bigcup_{n=0}^{\infty} \rho_n \\ &= h \circ I_D = h, \end{aligned}$$

so the given h is in fact the least fixed point. The homomorphism is uniquely determined, and D is the initial T-algebra. □

Having the existence of initial T-algebras, we can prove one more result that shows just how minimal they are. We need a lemma about projection pairs, first, that shows where sub-domains fit in. We write $D \trianglelefteq E$ as short for $D \cong D'$ for some $D' \triangleleft E$ in the following. The lemma gives a converse to 6.12.

LEMMA 6.15. For two neighbourhood systems D and E, if there exist a projection pair

$$i : D \to E \quad \text{and} \quad j : E \to D$$

with $j \circ i = I_D$ and $i \circ j \subseteq I_E$, then $D \trianglelefteq E$.

Proof. What we want to show is that i maps finite elements to finite elements, and that the desired D' is the image of D in E.

Suppose $X \in D$. We can write:

$$i(\uparrow X) = \bigcup\{\uparrow Y \mid Y \in i(\uparrow X)\}\ .$$

Applying j to both sides we have:

$$\uparrow X = j \circ i(\uparrow X) = \bigcup\{j(\uparrow Y) \mid Y \in i(\uparrow X)\}.$$

But then, since $X \in \uparrow X$, we find $X \in j(\uparrow Y)$ for some $Y \in i(\uparrow X)$. This implies

$$\uparrow X \subseteq j(\uparrow Y);\ \text{and so}\ i(\uparrow X) \subseteq i \circ j(\uparrow Y) \subseteq \uparrow Y.$$

Since $\uparrow Y \subseteq i(\uparrow X)$ in any case, we conclude $i(\uparrow X) = \uparrow Y$. This proves finite elements are mapped to finite elements.

What of Δ; that is, what is $i(\uparrow \Delta)$? We find, supposing E to be a neighbourhood system over a set Δ', that since $\uparrow \Delta \subseteq j(\uparrow \Delta')$, then $i(\uparrow \Delta) \subseteq \uparrow \Delta'$ and so $i(\uparrow \Delta) = \uparrow \Delta'$. This means that Δ corresponds to Δ'. So we have established that $\mathcal{D}$ is in an inclusion preserving one-one correspondence with a subset $\mathcal{D}'$ of E where $\Delta' \in \mathcal{D}'$. But it remains to show that $\mathcal{D}'$ is a neighbourhood system and that $\mathcal{D}' \triangleleft E$ holds. All we really have to show is that $\mathcal{D}'$ is closed under intersection whenever the intersection belongs to E.

Suppose $Y', Z' \in \mathcal{D}'$ and $Y' \cap Z' \in E$. Let $X' = Y' \cap Z'$. We have, for suitable $Y, Z \in \mathcal{D}$,

$$i(\uparrow Y) = \uparrow Y',\ \text{and so}\ \uparrow Y = j(\uparrow Y');\ \text{and}$$

$$i(\uparrow Z) = \uparrow Z',\ \text{and so}\ \uparrow Z = j(\uparrow Z').$$

But $\uparrow Y' \subseteq \uparrow X'$ and $j(\uparrow Y') \subseteq j(\uparrow X')$; thus $Y \in j(\uparrow X')$. For similar reasons $Z \in j(\uparrow X')$. But then $X = Y \cap Z \in j(\uparrow X')$, and therefore $Y \cap Z \in \mathcal{D}$. (The element $j(\uparrow X')$ must be a filter.) Notice, however, that

$$\uparrow Y \subseteq \uparrow X,\ \text{and so}\ \uparrow Y' \subseteq i(\uparrow X);\ \text{and}$$

$$\uparrow Z \subseteq \uparrow X,\ \text{and so}\ \uparrow Z' \subseteq i(\uparrow X).$$

It follows that $Y' \cap Z' = X' \in i(\uparrow X)$. On the other hand we already knew $X \in j(\uparrow X')$, which implies $i(\uparrow X) \subseteq \uparrow X'$. We may thus conclude that $i(\uparrow X) = \uparrow X'$. In other words $X' \in \mathcal{D}'$. □

THEOREM 6.16. If on the category of domains and strict approximable maps the functor T is continuous on maps, and if D is an initial T-algebra, then for any system $E \cong T(E)$ we have $D \trianglelefteq E$.

Proof: There is a homomorphism $h : D \to E$. By 6.9 there is a homomorphism $g : E \to D$. Now $g \circ h : D \to D$ is also a homomorphism, so $g \circ h = I_D$ because D is initial. In view of 6.15, all we have to prove now is that $h \circ g \sqsubseteq I_E$.

Let the maps $i : T(D) \to D$ and $j : D \to T(D)$ give the isomorphism for D, and let $u : T(E) \to E$ and $v : E \to T(E)$ do the same for E. By the proof of 6.9 we know

$$g = i \circ T(g) \circ v \quad \text{and} \quad h = u \circ T(h) \circ j$$

and each of these maps is the least fixed point of its respective equation. Let

$$g_0 = \bot_{E \to D} \quad \text{and} \quad h_0 = \bot_{D \to E}$$

and define by recursion

$$g_{n+1} = i \circ T(g_n) \circ v \quad \text{and} \quad h_{n+1} = u \circ T(h_n) \circ j.$$

By the fixed-point calculation

$$g = \bigsqcup_{n=0}^{\infty} g_n \quad \text{and} \quad h = \bigsqcup_{n=0}^{\infty} h_n.$$

Now we see that

$$h_0 \circ g_0 = \bot_{E \to E},$$

and for each n that

$$\begin{aligned} h_{n+1} \circ g_{n+1} &= u \circ T(h_n) \circ j \circ i \circ T(g_n) \circ v \\ &= u \circ T(h_n) \circ T(g_n) \circ v \\ &= u \circ T(h_n \circ g_n) \circ v. \end{aligned}$$

But this means that

$$h \circ g = \bigsqcup_{n=0}^{\infty} (h_n \circ g_n)$$

is the least fixed point for the equation

$$k = u \circ T(k) \circ v.$$

But I_E is one of the fixed points; whence $h \circ g \sqsubseteq I_E$ must follow. □

EXERCISE 6.17. What are the algebras for which C is initial? If A of 6.2 is a generalization of B, what is the corresponding generalization of C? Prove that it exists and explain what are the algebras involved.

4.7.41 iterProdInitial — D^∞ initial

EXERCISE 6.18. With reference back to Exercise 3.16 discuss the construction of $\mathcal{D}^\infty$ as an initial algebra and as a solution to the domain equation

$$\mathcal{D}^\infty \cong \mathcal{D} \times \mathcal{D}^\infty.$$

(I do not know whether all solutions must be of the form $\mathcal{D}^\infty \times E$.)

4.7.44 Exercise 6.19 — strict sum and product

For the sake of uniformity restrict attention to systems $\mathcal{D}$ on sets $\Delta \subseteq \{0,1\}^*$, where $\Lambda \in \Delta$ and $\emptyset \notin \mathcal{D}$, and to the category of strict maps. Define sum and product by:

$$\mathcal{D}_0 + \mathcal{D}_1 = \{\{\Lambda\} \cup 0\Delta_0 \cup 1\Delta_1\} \cup \{0X \mid X \in \mathcal{D}_0\} \cup \{1Y \mid Y \in \mathcal{D}_1\},$$

$$\mathcal{D}_0 \times \mathcal{D}_1 = \{\{\Lambda\} \cup 0X \cup 1Y \mid X \in \mathcal{D}_0 \text{ and } Y \in \mathcal{D}_1\}.$$

Are these correct up to isomorphism? Now generate all constructs $T(X)$ formed by the constants (that is, $T(X) = \mathcal{D}$ for a fixed $\mathcal{D}$), by the identity ($T(X) = X$), and by sums and products ($T_0(X) + T_1(X)$, etc.). Show that these are all functors, continuous on maps, and monotone and continuous on domains.

4.7.46 Exercise 6.20 — tokens of a functor

NeighbourhoodSystems/DomainEquations/Exercise_6_20.lean

`Exercise_6_20.lean`

```
module

public import DomainTheory.NeighbourhoodSystems.DomainEquations.functorTokens

@[expose] public section

open DomainTheory.NeighbourhoodSystems

open NeighborhoodSystem ApproximableMap BitDom DomainTheory.NeighbourhoodSystems.
    FunctorTokens

/-- Scott's Exercise 6.20: `λΓ. tok(T({Γ}))` is continuous, hence a fixed point exists.
    -/
theorem example_620 :
    (∀ (T : FExpr), T.RootedConst → ∃ (Γ : Set Str), ([] : Str) ∈ Γ ∧ mFun T Γ = Γ) ∧
    (∀ (T : FExpr), T.RootedConst →
      ∃ (Γ : Set Str) (h : Γ.Nonempty),
        (singletonSys Γ h).sys ? (T.obj (singletonSys Γ h)).sys) :=
  ⟨@exists_tok_fixedPoint, @exists_singleton_subsystem⟩
```

EXERCISE 6.20. For any system $\mathcal{D}$ let $\mathrm{tok}(\mathcal{D})$ be the underlying set of tokens, so that $\mathcal{D}$ is a system over $\mathrm{tok}(\mathcal{D})$. For the category of Exercise 6.19 show that the function

$$\lambda\Gamma.\,\mathrm{tok}(T(\{\Gamma\}))$$

is continuous on the domain $\{\Gamma \subseteq \{0,1\}^* \mid \Lambda \in \Gamma\}$, where T is any of the functors generated in 6.19. Conclude that there must exist a set

$$\Gamma = \mathrm{tok}(T(\{\Gamma\})),$$

so that $\{\Gamma\} \triangleleft T(\{\Gamma\})$, and so 6.14 applies.

4.7.47 coalesceSmash — coalesced sum and smash

4.7.48 Exercise 6.21 — coalesced sum and smash

NeighbourhoodSystems/DomainEquations/Exercise_6_21.lean

`Exercise_6_21.lean`

```
module

public import DomainTheory.NeighbourhoodSystems.DomainEquations.coalesceSmash

@[expose] public section

open DomainTheory.NeighbourhoodSystems

open NeighborhoodSystem ApproximableMap SeqEqB BitDom DomainTheory.
    NeighbourhoodSystems.SmashProduct DomainTheory.NeighbourhoodSystems.FunctorTokens

/-- Scott's Exercise 6.21: rooted grammars admit a subsystem solution and a fixed-
    point set containing `[]`. -/
theorem example_621 :
    (∀ (T : GExpr), T.RootedConst →
      ∃ (Γ : Set Str) (h : Γ.Nonempty),
        (singletonSys Γ h).sys ? (T.obj (singletonSys Γ h)).sys) ∧
    (∀ (T : GExpr), T.RootedConst → ∃ (Γ : Set Str), ([] : Str) ∈ Γ ∧ gFun T Γ = Γ)
    :=
  ⟨@gExists_singleton_subsystem, @gExists_tok_fixedPoint⟩
```

EXERCISE 6.21. Do the same as 6.19 and 6.20 when the functors are also allowed to be generated by the operations:

$$D_0 \oplus D_1 = \{\{\Lambda\} \cup 0\Delta_0 \cup 1\Delta_1\} \cup \{0X \mid X \in D_0 \setminus \{\Delta_0\}\} \cup \{1Y \mid Y \in D_1 \setminus \{\Delta_1\}\},$$

$$D_0 \otimes D_1 = \{\{\Lambda\} \cup 0\Delta_0 \cup 1\Delta_1\} \cup \{\{\Lambda\} \cup 0X \cup 1Y \mid X \in D_0 \setminus \{\Delta_0\} \text{ and } Y \in D_1 \setminus \{\Delta_1\}\}.$$

Generalize all of $+$, $\times$, $\oplus$, $\otimes$ to combinations of several terms, not just the binary sums and products.

```

EXERCISE 6.23. Construe the initial solution to

$$Exp \cong N \oplus ((Exp \times Exp) + (Exp \times Exp))$$

as a "syntactical domain" of expressions generated from infinitely many "variables" by means of two binary "operation symbols". Given an algebra D with two operations

$$u : D \times D \to D \quad \text{and} \quad v : D \times D \to D,$$

show how any strict map $s : N \to D$ determines a unique map

$$val(s) : Exp \to D$$

that can be regarded as the "evaluation of an expression".

  ⟨RecDomainEq.Dsol, RecDomainEq.Esol, RecDomainEq.Dsol_subsystem, RecDomainEq.
    Esol_subsystem⟩
```

EXERCISE 6.24. Show that there must exist domains satisfying:

$$D \cong D + (D \times E), \quad \text{and}$$

$$E \cong D + E,$$

by using a double fixed-point method. First decide what the underlying set of tokens should be, and then define D and E by simultaneous fixed points. (Syntactical domains as in 6.23 may very well require several simultaneous equations.)

```

EXERCISE 6.25. For a projection pair $g : \mathcal{D} \to \mathcal{E}$ and $h : \mathcal{E} \to \mathcal{D}$ show that for $x \in |\mathcal{D}|$ and $y \in |\mathcal{E}|$ we have:

$$g(x) \sqsubseteq y \text{ iff } x \sqsubseteq h(y).$$

Thus, conclude that:

$$h(y) = \bigsqcup\{x \in |\mathcal{D}| \mid g(x) \sqsubseteq y\}, \quad \text{and}$$

$$g(x) = \bigsqcap\{y \in |\mathcal{E}| \mid x \sqsubseteq h(y)\},$$

for all $x \in |\mathcal{D}|$ and $y \in |\mathcal{E}|$. So each of the functions determines the other. In the first equation check that the set on the right is directed, and in the second equation that the set on the right is non empty. Prove also that g maps consistent sets to consistent sets and preserves $\bigsqcup$ (not just directed unions).

EXERCISE 6.26. For systems $\mathcal{D}$ as in 6.19 define

$$\mathcal{D}_\perp = \{\{\Lambda\} \cup 0\Delta\} \cup \{0X \mid X \in \mathcal{D}\}.$$

Describe the construct in terms of elements. Is this a suitable functor? Prove that

$$\mathcal{D}_\perp \oplus \mathcal{E}_\perp \cong \mathcal{D} + \mathcal{E}.$$

What is

$$\mathcal{D}_\perp \otimes \mathcal{E}_\perp \cong ??$$

4.7.64 Exercise 6.29 — infinitary sum and product

Generalize $+$ and $\times$ to infinitary operations on domains:

$$\sum_{n=0}^{\infty} D_n \quad \text{and} \quad \prod_{n=0}^{\infty} D_n.$$

Would a similar generalization be possible for $\oplus$ and $\otimes$?

4.8 Computability in effectively given domains

<!DOCTYPE svg PUBLIC “-//W3C//DTD SVG 1.1//EN” “http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd”>

Figure 52: Diagram 17

4.8.1 Introduction

For the domain N the strict functions from N into N, the strict maps $f : N \to N$, correspond exactly to the partial functions $g : N \to N$ (as we wrote in 5.6 we had $f = \bar{g}$). For such functions there is a standard theory of computability: g is called computable if it can be defined as a partial recursive function with its "program" written down in a certain standard form. The non-strict maps $h : N \to N$ are all constant, and so are intuitively computable; so we know all about computable maps in $|N \to N|$ in general. The question is: what are the computable maps on (elements of) other domains?

The answer will of course depend on how the domain is presented to us. Even with N, there are continuum many isomorphisms $\pi : N \to N$ of N onto itself, not all of which can be computable. That is, if we permute N and, so to speak, present the integers in a different order, then a well-behaved computable function $f : N \to N$ may well be transformed into a non-computable function,

$$\pi \circ f \circ \pi^{-1} : N \to N.$$

(Hint: Consider the characteristic function e of the even numbers. Take $f = \bar{e}$ and let π be very horrid.) The reason we imagined we knew which were the computable $f : N \to N$ is that N is always thought of in a standard presentation. We must thus define "in general" a concept of an *effectively given domain*, that is to say, one with a sufficiently computable presentation to represent the additional knowledge about the domain.

The main idea will be that the *finite elements* of $|D|$ should be regarded as the ones initially known. Abstractly, to know a finite element is to know how it is *related* to other finite elements.

Of course, this will mean that we will allow at most a countable infinity of finite elements — but this restriction well accords with intuition. To make precise the terminology "related to" it proves most convenient to go back to the neighbourhoods (in any case they are in a one-one correspondence with the finite elements).

4.8.2 Recursive predicates

Recursively enumerable and recursively decidable predicates on the natural numbers, together with the primitive-recursive coding of lists used to present neighbourhoods.

Theorem (`amGM`). For natural numbers, four times their product is at most the square of their sum.

Proof. Expanding the square reduces the inequality to nonnegativity of the square of the difference of the two numbers. ■

Theorem (`iter_sq_le`). Every value returned by the square-root iteration has square at most the input.

Proof. Induction over the square-root iteration uses the arithmetic–geometric mean inequality to show that each positive update remains below the input after squaring; the zero branch is immediate. ■

Theorem (`lt_of_mul_lt_mul_left'`). A strict inequality after multiplication by a common natural factor implies the corresponding strict inequality of the other factors.

Proof. A strict product inequality forces the common factor to be positive; cancellation of that positive factor then gives the strict inequality between the remaining factors. ■

Theorem (`lt_iter_succ_sq`). If the input lies below the square of one more than an initial guess, it also lies below the square of one more than the resulting square-root iterate.

Proof. Induction on the iteration compares the arithmetic-mean update with the preceding guess; the arithmetic–geometric mean estimate and cancellation of a positive factor preserve the strict upper-square bound. ■

Theorem (`lt_succ_sqrt`). Every natural number is strictly below the square of one more than its square root.

Proof. The square root satisfies the lower-square bound, and the next consecutive square is therefore strictly above the input by the interval characterization. ■

Theorem (`sqrt_le`). The square of the natural square root of a number is at most that number.

Proof. The square-root iteration already has square at most the input, and the natural square root is the iteration begun from the input itself. ■

Theorem (`sqrt_eq_of`). If a number lies between two consecutive squares beginning at the square of a given integer, its natural square root is that integer.

Proof. The two hypotheses place the number in the unique interval from one square up to the next consecutive square. ■

Theorem (`sqrt_add_eq`). Adding at most twice an integer to its square does not change its natural square root.

Proof. The hypothesis places the added term below twice the base, so the result lies from the base square up to, but not including, the next square; the square-root interval characterization applies. ■

Theorem (`unpair_pair`). Unpairing a paired pair of natural numbers recovers the original ordered pair.

Proof. Substitution of the explicit pairing formula identifies its square-root block; the resulting quotient and offset calculations recover both entries. ■

Theorem (`unpair_pair_fst`). The first component obtained by unpairing a paired pair is its first entry.

Proof. Taking first components in the pairing inverse identity recovers the first entry. ■

Theorem (`unpair_pair_snd`). The second component obtained by unpairing a paired pair is its second entry.

Proof. Taking second components in the pairing inverse identity recovers the second entry. ■

Definition (`selectFn`). This selector returns its first value when its numerical control is one and its second value when the control is zero.

Theorem (`selectFn_one`). A selector controlled by one returns its first value.

Proof. Substitution of control one cancels the second summand and leaves the first value. ■

Theorem (`selectFn_zero`). A selector controlled by zero returns its second value.

Proof. Substitution of control zero cancels the first summand and leaves the second value. ■

Theorem (`selectFn_ite`). A zero-one control obtained from a proposition makes numerical selection agree with ordinary case distinction.

Proof. In the true case the Boolean control is one and in the false case it is zero; the two selector equations settle the cases. ■

Definition (`RecDecidable`). A predicate on natural numbers is recursively decidable when a primitive-recursive characteristic function takes the value one exactly on its true instances.

Definition (`REPred`). A predicate on natural numbers is recursively enumerable when membership is the existence of a numerical witness satisfying a recursively decidable relation.

Definition (`REPred2`). A binary predicate is recursively enumerable when its pullback along the fixed pairing of natural numbers is recursively enumerable.

Definition (`RecDecidable2`). A binary predicate is recursively decidable when its pullback along the fixed pairing of natural numbers is recursively decidable.

Definition (`RecDecidable3`). A ternary predicate is recursively decidable when the predicate obtained by nested pairing is recursively decidable.

Definition (`encodeList`). The empty list is coded by zero, and a nonempty list is coded by pairing its head with the code of its tail and then taking the successor.

Definition (`foldStep`). A coded fold step either leaves a terminal state fixed or removes the next coded list entry and updates the accumulator with the given step operation.

Definition (`foldCode`). The fold of a coded list iterates the coded fold step for a bounded number of stages and returns the resulting accumulator.

Definition (`halfParity`). This primitive recursion simultaneously records the quotient and remainder of a natural number on division by two.

Definition (`isOne`). This zero-one characteristic function has value one exactly at the natural number one.

Theorem (`isOne_eq_one_iff`). The characteristic of one has value one exactly at the input one.

Proof. Expanding the two truncated differences shows that their sum vanishes exactly when the input is neither below nor above one. ■

Theorem (`isOne_one`). The characteristic of one evaluates to one at one.

Proof. Substituting one makes both truncated differences zero, leaving one. ■

Theorem (`isOne_zero`). The characteristic of one evaluates to zero at zero.

Proof. Substituting zero makes the second truncated difference one, which is subtracted from one. ■

Definition (`allListStp`). This fold step preserves a success flag precisely when the current coded list entry satisfies the given characteristic function.

Definition (`allListChar`). This characteristic function tests whether every entry of a coded list satisfies a given numerical predicate.

Definition (`bExistsFn`). This bounded search characteristic records whether some index below the bound satisfies the given numerical predicate.

Definition (`bForallFn`). This bounded search characteristic records whether every index below the bound satisfies the given numerical predicate.

Definition (`existsListStp`). This fold step records whether the current coded list entry or an earlier entry satisfies the given characteristic function.

Definition (`existsListChar`). This characteristic function tests whether some entry of a coded list satisfies a given numerical predicate.

Definition (`isBinDigit`). This characteristic function recognizes exactly the two binary digits zero and one.

Definition (`allBinDigitsChar`). This characteristic function tests whether every entry of a coded list is a binary digit.

Definition (`isZero`). This zero-one characteristic function has value one exactly at zero.

Theorem (`le_pair_right`). Each component of a paired natural number is at most the pair code.

Proof. Expanding the pairing formula leaves the second component plus nonnegative terms. ■

Definition (`listLenStp`). This fold step increments the accumulated length by one.

Definition (`listLenChar`). This numerical function computes the length of the list represented by a code.

Definition (`lowOr`). This operation computes the lowest binary digit of the bitwise disjunction of two natural numbers.

Definition (`lorStep`). This state transition removes the lowest bits of two numbers while accumulating their bitwise disjunction.

Definition (`mapPairStep`). This operation adjoins the pair formed from a fixed parameter and a list entry to an accumulated list code.

Definition (`mapPairStp`). This packed fold step applies the operation that pairs every list entry with a fixed parameter.

Definition (`mapPairCode`). This operation codes the list obtained by pairing a fixed natural number with every entry of a coded list.

Definition (`mulBit`). This operation combines two zero-one values by multiplication, thereby representing conjunction.

Definition (`decodeFuelOkCharBody`). This one-stage characteristic interprets a tagged code using previously computed values for its recursive subcodes.

Definition (`decodeFuelOkChar`). This fuel-bounded characteristic evaluates well-formedness of coded expressions by recursion on the available fuel.

Definition (`myLor`). This operation computes binary disjunction by repeatedly consuming the low bits of its two arguments.

Definition (`natEqChar`). This zero-one characteristic function recognizes equality of two natural numbers.

Theorem (`natEqChar_eq_one_iff`). The natural-number equality characteristic has value one exactly when its two arguments are equal.

Proof. The two opposite truncated differences vanish simultaneously exactly when the arguments are equal. ■

Definition (`codeBound`). This recursively defined bound dominates every code of a sufficiently short list of binary digits.

Definition (`listEqStpNonzero`). This comparison step consumes one entry from a nonempty remaining list code and preserves the equality flag exactly when the entries agree.

Definition (`listEqStp`). This comparison step handles the empty-list case and otherwise advances the coded list comparison.

Definition (`listEqChar`). This characteristic function tests equality of the two lists represented by given codes.

Definition (`listEqStep`). This unpacked comparison step applies one coded-list equality update to a state and a new entry.

Definition (`nthStp`). This fold step counts list positions and retains the entry at the requested index, using a prescribed default if none is found.

Definition (`nthCode`). This operation returns the requested entry of a coded list, or a prescribed default beyond its length.

Definition (`appendListTabFn`). This table entry function reads first from one coded list and then from a second, with the split determined by the first length.

Definition (`decodeFuelOkCharLookup`). This table-based evaluator performs one tagged well-formedness step using prior values stored in a coded table.

Definition (`dropListTabFn`). This table entry function reads a coded list after shifting its index by the number of entries to discard.

Definition (`reForallF`). This update consumes one witness code and preserves a success flag when the corresponding decidable relation holds.

Definition (`reForallStp`). This packed update advances the witness-list test for universal membership in a recursively enumerable predicate.

Definition (`reForallChar`). This characteristic checks a list of proposed witnesses against the corresponding entries of another coded list.

Theorem (`sqrt_le_add`). Every natural number is at most the square of its natural square root plus twice that square root.

Proof. The input is below the next square, whose expansion is the square-root square plus twice the square root plus one; natural-number discreteness removes the final one. ■

Theorem (`pair_unpair`). Pairing the two components obtained by unpairing a natural number recovers that number.

Proof. The square-root bounds locate the number in its triangular pairing block; substituting the resulting quotient and offset reconstructs it. ■

Definition (`tabStep`). This recursion step adjoins the next value of a finite numerical table to its code.

Definition (`tabCode`). This operation codes the finite table of values of a numerical function below a given bound.

Definition (`appendListCode`). This operation produces a code for the concatenation of two coded lists.

Definition (`dropCode`). This operation produces a code for the list obtained after deleting a prescribed initial segment.

Definition (`fuelTableStep`). This operation constructs the next finite table of fuel-bounded values from the preceding table.

Definition (`fuelTable`). This primitive recursion builds the finite table of all fuel-bounded values below a prescribed code bound.

Definition (`takeListTabFn`). This table entry function reads an entry of a coded list at the table index.

Definition (`takeCode`). This operation produces a code for the prescribed initial segment of a coded list.

Theorem (`unpair_snd_le`). The second component obtained by unpairing a natural number is at most that number.

Proof. The second component is bounded by its reconstructed pair, and pairing the two unpaired components returns the original number. ■

Definition (`decodeList`). Zero decodes to the empty list, while a successor code decodes by unpairing its predecessor into the head and the code of the tail.

Theorem (`primrec_id`). The numerical function defining id is primitive recursive.

Proof. The identity is the first projection after pairing the input with zero, hence is primitive recursive. ■

Theorem (`rec_add`). The displayed primitive recursion computes add on natural numbers.

Proof. Induction on the second argument matches zero with the initial value and each successor with one further increment. ■

Theorem (`rec_mul`). The displayed primitive recursion computes mul on natural numbers.

Proof. Induction on the second argument turns the successor equation into one further addition, matching multiplication by a successor. ■

Theorem (`primrec_add`). The numerical function defining add is primitive recursive.

Proof. Primitive recursion from the first input, adding one at each successor of the second, computes addition. ■

Theorem (`primrec_mul`). The numerical function defining mul is primitive recursive.

Proof. The mul construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`rec_pred`). The displayed primitive recursion computes pred on natural numbers.

Proof. The zero clause returns zero, while at a successor the recursion returns the preceding index. ■

Theorem (`primrec_pred`). The numerical function defining pred is primitive recursive.

Proof. Primitive recursion returns the predecessor stage at each successor and zero at the base. ■

Theorem (`rec_sub`). The displayed primitive recursion computes sub on natural numbers.

Proof. Induction on the second argument matches zero subtraction and one further predecessor at each successor. ■

Theorem (`primrec_sub`). The numerical function defining sub is primitive recursive.

Proof. Primitive recursion from the first input applies predecessor once for each unit of the second input. ■

Theorem (`nat_mul_eq_one`). A product of natural numbers is one exactly when both factors are one.

Proof. Unique factorization of one in the natural numbers forces each factor to be one, and the converse is immediate by multiplication. ■

Theorem (`primrec_add2`). The numerical function defining add2 is primitive recursive.

Proof. The add2 construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_mul2`). The numerical function defining mul2 is primitive recursive.

Proof. The mul2 construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_sub2`). The numerical function defining sub2 is primitive recursive.

Proof. The sub2 construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_selectFn`). The numerical function defining selectFn is primitive recursive.

Proof. The select function construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`RecDecidable.of_iff`). A predicate pointwise equivalent to a recursively decidable predicate is recursively decidable.

Proof. Use the same primitive-recursive characteristic and replace its truth specification by the given pointwise equivalence. ■

Theorem (`RecDecidable.comp`). The pullback of a recursively decidable predicate along a primitive-recursive function is recursively decidable.

Proof. Compose the witnessing zero–one characteristic with the primitive-recursive input function. ■

Theorem (`RecDecidable.and`). The conjunction of two recursively decidable predicates is recursively decidable.

Proof. Multiply the two zero–one characteristic functions, so the result is one exactly when both original predicates hold. ■

Theorem (`RecDecidable.natEq`). Equality of the values of two primitive-recursive natural-number functions is recursively decidable.

Proof. Compare the two primitive-recursive values in both directions by truncated subtraction; both differences vanish exactly when the values are equal. ■

Theorem (`RecDecidable.not`). The complement of a recursively decidable predicate is recursively decidable.

Proof. Subtract the zero–one characteristic from one; this exchanges its accepting and rejecting values. ■

Theorem (`RecDecidable.em`). Every instance of a recursively decidable predicate either holds or fails.

Proof. The witnessing characteristic has a definite natural value; its specification decides whether the predicate holds. ■

Theorem (`RecDecidable.or`). The disjunction of two recursively decidable predicates is recursively decidable.

Proof. Use the zero–one test of the sum of the two characteristics; the sum is positive exactly when at least one predicate holds. ■

Theorem (`RecDecidable.re`). Every recursively decidable predicate is recursively enumerable.

Proof. Introduce a dummy existential witness and use the original decidable predicate as the witness relation. ■

Theorem (`RecDecidable2.re`). Every recursively decidable binary relation is recursively enumerable.

Proof. Apply the decidable-to-enumerable conversion after encoding the two arguments by pairing. ■

Theorem (`REPred.of_iff`). A predicate pointwise equivalent to a recursively enumerable predicate is recursively enumerable.

Proof. Keep the same decidable witness relation and transport its existential characterization through the pointwise equivalence. ■

Theorem (`REPred.comp`). The pullback of a recursively enumerable predicate along a primitive-recursive function is recursively enumerable.

Proof. Apply the primitive-recursive input map to the object coordinate while retaining the existential witness coordinate. ■

Theorem (`REPred.and`). The conjunction of two recursively enumerable predicates is recursively enumerable.

Proof. Multiply the two zero–one characteristic functions, so the result is one exactly when both original predicates hold. ■

Theorem (`REPred.proj`). Existential projection of a recursively enumerable predicate along the first paired coordinate is recursively enumerable.

Proof. Pair the input with an existential witness and absorb the witness into the existential quantifier already present in recursive enumerability. ■

Theorem (`REPred.or`). The disjunction of two recursively enumerable predicates is recursively enumerable.

Proof. Combine the two zero–one characteristics by bounded addition, which is positive exactly when at least one predicate holds. ■

Theorem (`le_pair_left`). Each component of a paired natural number is at most the pair code.

Proof. Expanding the pairing formula leaves the first component plus nonnegative terms. ■

Theorem (`encodeList_length_le`). The length of a finite list is at most its natural-number code.

Proof. Induction on the list uses the tail bound and the fact that a pair code dominates its second component. ■

Theorem (`foldStep_zero`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. A zero remaining code activates the terminal branch, which preserves the packed accumulator state. ■

Theorem (`foldStep_pos`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. For a successor list code, subtracting one exposes its paired head and tail; the nonempty branch advances the tail and updates the accumulator. ■

Theorem (`rec_const_iterate`). The displayed primitive recursion computes const iterate on natural numbers.

Proof. Induction on the iteration count identifies the base state and one further application of the function. ■

Theorem (`foldStep_iterate`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. Induction on the fuel follows the empty-list fixed point or consumes one encoded head; the length bound guarantees enough fuel for the tail. ■

Theorem (`foldCode_eq`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. The code supplies at least the decoded list length as fuel, so the fold-step iteration theorem yields the ordinary left fold. ■

Theorem (`unpair_left_le`). The first component obtained by unpairing a natural number is at most that number.

Proof. The first component is bounded by its pair code, and pairing the two unpaired components reconstructs the original number. ■

Theorem (`pair_le_pair_left`). Increasing the first component while fixing the second cannot decrease the pair code.

Proof. Strict monotonicity of pairing in the first coordinate handles the strict case, while equality is immediate. ■

Theorem (`pair_le_pair_right'`). Increasing the second component while fixing the first cannot decrease the pair code.

Proof. Strict monotonicity of pairing in the second coordinate handles the strict case, while equality is immediate. ■

Theorem (`pair_le_pair`). Increasing both components cannot decrease the pair code.

Proof. First increase the first coordinate and then the second, composing the two coordinatewise monotonicity results. ■

Theorem (`decodeList_zero`). Zero decodes to the empty list.

Proof. The zero clause of decoding is the empty list. ■

Theorem (`decodeList_succ`). A successor code decodes to the first unpaired component of its predecessor followed by the decoding of the second component.

Proof. The successor clause unpairs the predecessor into the head and recursively decoded tail. ■

Theorem (`encodeList_decodeList`). Encoding the list decoded from a natural number recovers that number.

Proof. Strong induction on the code uses the strictly smaller tail component and reconstruction by pairing. ■

Theorem (`foldCode_eq'`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. Encode the decoded list without changing the code, then apply the coded-fold theorem to that list. ■

Theorem (`primrec_foldStepPacked`). The numerical function defining foldStepPacked is primitive recursive.

Proof. The foldStepPacked construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_foldCode`). The numerical function defining foldCode is primitive recursive.

Proof. The foldCode construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`isOne_le_one`). The characteristic of one is always at most one.

Proof. Its definition subtracts a natural number from one, so truncated subtraction cannot exceed one. ■

Theorem (`isOne_of_ne_one`). At every input other than one, the characteristic of one is zero.

Proof. If the input is below or above one, one of the two opposite truncated differences is positive, forcing the final subtraction to zero. ■

Theorem (`primrec_isOne`). The numerical function defining isOne is primitive recursive.

Proof. The isOne construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`isZero_eq_one_iff`). The zero characteristic has value one exactly at zero.

Proof. The minimum with one is zero exactly at zero; subtracting it from one gives the claimed truth condition. ■

Theorem (`isZero_le_one`). The zero characteristic is always at most one.

Proof. It is obtained by truncated subtraction from one, and therefore cannot exceed one. ■

Theorem (`primrec_isZero`). The numerical function defining isZero is primitive recursive.

Proof. The isZero construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_le`). The numerical function defining le is primitive recursive.

Proof. The le construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`bForallFn_le_one`). The bounded universal characteristic is always at most one.

Proof. Induction on the bound starts at one and each new selector returns either zero or a one-characteristic, both at most one. ■

Theorem (`bForallFn_eq_one_iff`). The bounded universal characteristic is one exactly when the tested function is one at every index below the bound.

Proof. Induction on the bound separates the previous indices from the new final index; the binary accumulator remains one precisely when both parts succeed. ■

Theorem (`bExistsFn_le_one`). The bounded existential characteristic is always at most one.

Proof. Induction on the bound observes that an already successful search stays at one, while an unsuccessful search takes the next one-characteristic, which is binary. ■

Theorem (`bExistsFn_congr`). Two bounded existential searches agree when their tested values agree at every index below the bound.

Proof. Induction on the bound uses agreement on all earlier indices for the recursive value and agreement at the new final index for the next update. ■

Theorem (`bExistsFn_eq_one_iff`). The bounded existential characteristic is one exactly when some index below the bound has tested value one.

Proof. Induction on the bound splits a witness below the previous bound from the newly added final index and follows the two selector cases. ■

Theorem (`primrec_bExistsFn`). The numerical function defining bExistsFn is primitive recursive.

Proof. The bExists function construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_bExistsFn_param`). The numerical function defining bExistsFn param is primitive recursive.

Proof. The bExists function param construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`decodeList_encodeList`). Decoding the code of a finite list recovers the list.

Proof. Induction on the list or code uses the successor coding equation and the fact that unpairing a freshly paired head and tail recovers both components. ■

Theorem (`reForallStp_eq`). Unpacking one universal-witness step yields the update that consumes the next witness and list entry.

Proof. Unpairing the current list entry, witness code and flag gives exactly the unpacked witness-checking update. ■

Theorem (`reForallChar_eq`). The coded universal-witness characteristic is the final flag of the corresponding fold over the decoded list.

Proof. The coded-fold equation turns the packed step into the unpacked witness-checking update over the decoded list. ■

Theorem (`reForallF_foldl_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. Induction on the candidate list tracks the binary flag and aligns each entry with the same-position witness obtained by decoding the witness code. ■

Theorem (`reForallChar_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. Specializing the fold characterization to initial flag one leaves exactly the pointwise witness checks below the decoded length. ■

Theorem (`primrec_reForallStp`). The numerical function defining reForallStp is primitive recursive.

Proof. The reForall step construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_reForallChar`). The numerical function defining reForallChar is primitive recursive.

Proof. The reForall characteristic construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`REPred.forall_mem_decodeList`). If a predicate is recursively enumerable, then the property that every member of a decoded finite list satisfies it is recursively enumerable.

Proof. Encode one witness for each list position into a witness list; the universal witness checker verifies all positions, and conversely each accepted position supplies a witness for the corresponding member. ■

Theorem (`lowOr_eq_mod`). The recursive binary-digit calculation agrees with ordinary quotient, remainder, or bitwise disjunction.

Proof. The four possible pairs of low bits agree with the low bit of binary disjunction. ■

Theorem (`lor_low_rec`). The recursive binary-digit calculation agrees with ordinary quotient, remainder, or bitwise disjunction.

Proof. Division by two shifts every test bit down one place, while the remainder formula restores the low disjunction bit. ■

Theorem (`lorStep_iter_spec`). After the specified number of binary-disjunction steps, both inputs have been divided by the corresponding power of two, the place value equals that power, and the accumulator plus the unprocessed high part equals the original disjunction.

Proof. Induction on the iteration count tracks the halved inputs, doubling place value, and accumulated low bits; the one-step binary recurrence preserves the invariant. ■

Theorem (`myLor_eq_lor`). The recursive binary-digit calculation agrees with ordinary quotient, remainder, or bitwise disjunction.

Proof. After enough halvings both remaining inputs are zero, so the iteration invariant identifies the accumulator with the full binary disjunction. ■

Theorem (`allListStp_eq`). Unpacking one universal-list step yields conjunction of the old flag with the current entry test.

Proof. Unpairing the packed entry, accumulator and parameter gives the selector that conjoins the old flag with the current test. ■

Theorem (`allListChar_eq`). The universal-list characteristic is the conjunction fold of the entry tests over the decoded list.

Proof. The coded-fold equation and the unpacked step equation identify the characteristic with the displayed conjunction fold. ■

Theorem (`allList_foldl_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. Induction on the list uses the binary accumulator: success after the head and tail means initial success and every entry test equals one. ■

Theorem (`allListChar_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. Apply the conjunction-fold characterization with initial accumulator one. ■

Theorem (`allListChar_le_one`). The characteristic function always takes a value at most one.

Proof. Induction on the decoded list preserves the bound because each update returns either zero or a one-characteristic. ■

Theorem (`primrec_allListStp`). The numerical function defining allListStp is primitive recursive.

Proof. The allList step construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`isBinDigit_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. The cases zero and one activate an accepting selector branch, while every value at least two reaches the rejecting branch. ■

Theorem (`primrec_isBinDigit`). The numerical function defining isBinDigit is primitive recursive.

Proof. The isBinDigit construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`allBinDigitsChar_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. The universal-list characterization says every decoded entry passes the binary-digit test, whose truth condition is being zero or one. ■

Theorem (`allBinDigitsChar_le_one`). The characteristic function always takes a value at most one.

Proof. This is the universal-list bound specialized to the binary-digit characteristic. ■

Theorem (`primrec_allBinDigitsChar`). The numerical function defining allBinDigitsChar is primitive recursive.

Proof. The allBinDigits characteristic construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`nthStp_val`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Unpairing the state increments the running position and selects the current entry exactly when that position equals the requested index. ■

Theorem (`nthCode_foldl`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Induction on the list compares the requested index with the running position, preserving the previous result before the position and replacing it exactly at equality. ■

Theorem (`nthCode_eq`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. The coded-fold equation starts the lookup fold at position zero, so the fold specification is ordinary list lookup with the given default. ■

Theorem (`primrec_nthStp`). The numerical function defining nthStp is primitive recursive.

Proof. The nth step construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_nthCode`). The numerical function defining nthCode is primitive recursive.

Proof. The nthCode construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`tabStep_val`). One table-building step adjoins the value at the next descending index to the accumulated table code.

Proof. Unpairing the bound, parameter, stage and prior code exposes the next descending table index and adjoins its value. ■

Theorem (`decodeList_tabCode_aux`). Decoding a partially built table yields the mapped interval of indices from the remaining bound through the processed entries.

Proof. Induction on the number of table entries shows that each step prepends the next descending index value to the already decoded suffix. ■

Theorem (`decodeList_tabCode`). Decoding a complete table code yields the values of the function on all indices below the bound.

Proof. Specialize the auxiliary decoding formula to the full bound, where the descending range becomes the ordinary initial range. ■

Theorem (`getD_eq_getElem_cf`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Induction on the list and index reduces in-range defaulted lookup to ordinary indexed lookup. ■

Theorem (`getD_eq_default_cf`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Induction on the list and index shows that an index at least the length repeatedly passes the head and eventually returns the default. ■

Theorem (`getD_map_range_cf`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. The mapped range has the prescribed length, and in-range lookup first selects its index from the range and then applies the map. ■

Theorem (`tabCode_nth_lt`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Decode the table as the mapped initial range and apply the in-range lookup formula. ■

Theorem (`tabCode_nth_ge`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Decode the table as a list of the bound length and apply the out-of-range default formula. ■

Theorem (`primrec_tabStep`). The numerical function defining tabStep is primitive recursive.

Proof. The tabStep construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_tabCode`). The numerical function defining tabCode is primitive recursive.

Proof. The tabCode construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_tagCase4`). The numerical function defining tagCase4 is primitive recursive.

Proof. The tagCase4 construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`mulBit_eq_one_iff`). The product of two binary characteristics is one exactly when both are one.

Proof. A product of natural numbers equals one only when both factors equal one, and the converse follows by multiplication. ■

Theorem (`mulBit_le_one`). The product of two characteristics bounded by one is itself bounded by one.

Proof. Each factor is zero or one; checking the four possible pairs gives a product no larger than one. ■

Theorem (`primrec_mulBit`). The numerical function defining mulBit is primitive recursive.

Proof. The mulBit construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`decodeFuelOkCharBody_eq`). The fuel-decoding body recognizes the four tags as the base, binary-list, conjunction and conjunction cases, and rejects every larger tag.

Proof. A case split on tags zero through three yields the base test, binary-list test and two recursive conjunction cases; all larger tags return zero. ■

Theorem (`primrec_decodeFuelOkCharBody`). The numerical function defining decodeFuelOkCharBody is primitive recursive.

Proof. The decodeFuelOk characteristicBody construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`decodeFuelOkCharBody_local`). The fuel-decoding body has the same value for two prior-stage functions that agree on every code no larger than the current code.

Proof. Only the two recursive subcodes can inspect the supplied functions, and both subcodes are no larger than the current code. ■

Theorem (`listLenStp_eq`). One packed length step increments the accumulated length by one.

Proof. Unpairing the packed state exposes the accumulated length, to which the step adds one. ■

Theorem (`listLenChar_eq`). The coded length function returns the length of the decoded list.

Proof. The coded fold becomes a fold that increments once per entry; induction on the decoded list shows that this fold counts its entries. ■

Theorem (`primrec_listLenStp`). The numerical function defining listLenStp is primitive recursive.

Proof. The listLen step construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_listLenChar`). The numerical function defining listLenChar is primitive recursive.

Proof. The listLen characteristic construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`natEqChar_le_one`). The natural-number equality characteristic is always at most one.

Proof. It is a truncated subtraction from one, so its value cannot exceed one. ■

Theorem (`natEqChar_eq_zero_or_one`). The natural-number equality characteristic is always zero or one.

Proof. The sum of opposite differences is either zero, leaving one, or positive, making the truncated subtraction zero. ■

Theorem (`primrec_natEqChar`). The numerical function defining natEqChar is primitive recursive.

Proof. The natEq characteristic construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`listEqStp_acc`). A packed list-comparison step fails on an empty remainder and otherwise compares the next entries while advancing the remainder.

Proof. Unpairing the state and separating whether the remaining code is zero gives exactly the failure branch and the nonempty comparison branch. ■

Theorem (`decodeList_eq_nil_iff`). A natural number decodes to the empty list exactly when it is zero.

Proof. Encoding both sides shows that an empty decoded list has code zero; the converse is the zero decoding equation. ■

Theorem (`selectFn_eq_one_iff_zero`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. The assumed binary control leaves the zero and one cases; direct evaluation gives conjunction in the one case and failure in the zero case. ■

Theorem (`listEqStep_zero`). Comparing another entry after the second coded list is exhausted produces a failed empty state.

Proof. The zero remainder activates the empty-remainder branch and returns the failed empty state. ■

Theorem (`listEqStep_succ`). With a nonempty second coded list, one comparison step combines the old flag with equality of the heads and advances to the tail code.

Proof. The zero test rejects the successor remainder; unpairing its predecessor supplies the next head and tail, and the equality characteristic updates the flag. ■

Theorem (`listEq_foldl_zero`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. After the second list is exhausted the next comparison sets the flag to zero, and induction shows that every remaining step preserves failure. ■

Theorem (`listEq_foldl_end_iff`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. Induction on the first list compares heads while both lists are nonempty, fails if the second ends early, and requires both successful flag and empty remainder at the end. ■

Theorem (`listEqChar_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. The final product is one exactly when the comparison flag is one and the remainder is empty; the fold characterization turns this into equality of decoded lists. ■

Theorem (`listEq_foldl_flag_le_one`). The characteristic function always takes a value at most one.

Proof. Induction on the first list preserves the binary flag because every comparison update uses binary selection and equality characteristic. ■

Theorem (`listEqChar_le_one`). The characteristic function always takes a value at most one.

Proof. Both the final comparison flag and empty-remainder test are at most one, so their product is at most one. ■

Theorem (`primrec_listEqStpNonzero`). The numerical function defining listEqStpNonzero is primitive recursive.

Proof. The listEq stepNonzero construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_listEqStp`). The numerical function defining listEqStp is primitive recursive.

Proof. The listEq step construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_listEqChar`). The numerical function defining listEqChar is primitive recursive.

Proof. The listEq characteristic construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`list_eq_of_getD`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. List extensionality uses equality of lengths and the assumed equality of defaulted lookups at every in-range position. ■

Theorem (`getD_take_cf`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Below the take length, lookup in the prefix agrees with lookup in the original list; beyond it, both use the default. ■

Theorem (`getD_drop_cf`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Lookup after dropping shifts the original index by the number discarded, with the default covering indices beyond the remaining suffix. ■

Theorem (`isZero_succ_sub_len1`). The zero test of one plus a truncated length difference records whether the first list is no longer than the second.

Proof. The truncated length difference is zero exactly when the first length does not exceed the second, and adding one makes the zero test reject precisely the opposite case. ■

Theorem (`isZero_succ_sub_len1_zero`). The same length test is zero precisely when the first list is strictly longer than the second.

Proof. Natural-number subtraction is positive exactly in the strict-length case, and the zero characteristic rejects every positive successor. ■

Theorem (`appendListTabFn_eq`). The coding operation agrees with concatenation or adjoining an entry to a finite list.

Proof. Below the first length the table reads the first list; at and above the split it reads the second list at the shifted index. ■

Theorem (`takeCode_eq`). Decoding the prefix code gives the requested initial segment of the decoded list.

Proof. Decode the generated table and compare each position with lookup in the original list to identify the requested prefix. ■

Theorem (`dropCode_eq`). Decoding the suffix code gives the decoded list after deleting the requested number of initial entries.

Proof. Decode the generated table and use shifted lookup to identify the suffix remaining after the requested deletion. ■

Theorem (`encodeList_take_le`). The code of an initial segment of a list is at most the code of the whole list.

Proof. A prefix is a sublist of the original list, and induction on the coding shows that encoding is monotone under removal of a tail. ■

Theorem (`encodeList_drop_le`). The code of a final segment of a list is at most the code of the whole list.

Proof. A suffix is obtained by repeated removal of heads, each of which cannot increase the list code. ■

Theorem (`takeCode_le`). A prefix code is at most the original list code.

Proof. Replace the generated code by the encoding of the decoded prefix and apply the prefix-code bound. ■

Theorem (`dropCode_le`). A suffix code is at most the original list code.

Proof. Replace the generated code by the encoding of the decoded suffix and apply the suffix-code bound. ■

Theorem (`primrec_takeListTabFn`). The numerical function defining takeListTabFn is primitive recursive.

Proof. The takeListTab function construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_min`). The numerical function defining min is primitive recursive.

Proof. The min construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_takeCode`). The numerical function defining takeCode is primitive recursive.

Proof. The takeCode construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_dropListTabFn`). The numerical function defining dropListTabFn is primitive recursive.

Proof. The dropListTab function construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_dropCode`). The numerical function defining dropCode is primitive recursive.

Proof. The dropCode construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`pair_lt_pair_zero_right`). Pairing zero with a strictly smaller second component gives a strictly smaller code.

Proof. Strict monotonicity of pairing in the second coordinate applies with first coordinate zero. ■

Theorem (`codeBound_ge`). The recursive code bound dominates every binary-list code of the prescribed length.

Proof. Induction on the length bounds the head binary digit and invokes the previous bound on the tail code before applying monotonicity of pairing. ■

Theorem (`RecDecidable2.swap`). Swapping the arguments of a recursively decidable binary relation preserves recursive decidability.

Proof. Precompose the paired characteristic with the primitive-recursive permutation that exchanges the two coordinates. ■

Theorem (`RecDecidable.bExists`). Bounded existential quantification of a recursively decidable relation is recursively decidable when the bound is primitive recursive.

Proof. A primitive-recursive bounded search accumulates disjunction of the characteristic values below the primitive-recursive bound. ■

Theorem (`RecDecidable.bForall`). Bounded universal quantification of a recursively decidable relation is recursively decidable when the bound is primitive recursive.

Proof. Encode the finitely many witnesses in one list, then use the decidable list checker to verify each corresponding entry; existential quantification over that witness list gives recursive enumerability. ■

Theorem (`RecDecidable.of_zero_one_char`). A primitive-recursive zero–one function that equals one exactly on a predicate makes that predicate recursively decidable.

Proof. Take the supplied primitive-recursive zero–one function as the characteristic; its assumed one-value condition is exactly the required specification. ■

Theorem (`RecDecidable2.of_paired_zero_one_char`). A primitive-recursive characteristic on paired arguments makes the corresponding binary relation recursively decidable.

Proof. Use the supplied primitive-recursive function directly as the characteristic after pairing the two arguments. ■

Theorem (`RecDecidable3.of_triple_zero_one_char`). A primitive-recursive characteristic on nested triples makes the corresponding ternary relation recursively decidable.

Proof. Use the supplied primitive-recursive function directly after encoding the three arguments by nested pairing. ■

Theorem (`codeBound_succ`). The code bound at a successor is obtained by pairing one with the previous bound and then taking the successor.

Proof. The successor equation is the defining recursive step of the code bound. ■

Theorem (`codeBound_zero`). The code bound at zero is zero.

Proof. The zero equation is the base clause of the code bound. ■

Theorem (`decodeFuelOkChar_le_one`). The characteristic function always takes a value at most one.

Proof. Induction on fuel separates the tag cases; constants and binary-list tests are bounded by one, while recursive conjunction multiplies two values already bounded by one. ■

Theorem (`decodeList_length_le`). The length of the list decoded from a natural number is at most that number.

Proof. Strong induction on the code removes the strictly smaller tail code and adds one entry, while the pairing bounds control the resulting length. ■

Theorem (`decodeList_mapPairStep`). Decoding one map-pair step prepends the pair of the fixed parameter and current entry to the decoded accumulator.

Proof. The adjoining decoding equation shows that one map step prepends the pair of the fixed parameter and current entry. ■

Theorem (`eqZero_bit`). The displayed binary control is one exactly in its zero case.

Proof. A value bounded by one is zero or one, and direct evaluation of the one-characteristic of its complement distinguishes the cases. ■

Theorem (`eq_of_le_one_iff_one`). For a natural number bounded by one, having one-characteristic equal to one is equivalent to being one.

Proof. The bound leaves only zero and one, and evaluation of the characteristic distinguishes those two values. ■

Theorem (`existsListStp_eq`). Unpacking one existential-list step yields disjunction of the old flag with the current entry test.

Proof. Unpairing the packed arguments yields the selector that preserves prior success or tests the current entry. ■

Theorem (`existsListChar_eq`). The existential-list characteristic is the disjunction fold of the entry tests over the decoded list.

Proof. The coded-fold equation and unpacked existential step identify the characteristic with a disjunction fold over the decoded list. ■

Theorem (`existsListChar_le_one`). The characteristic function always takes a value at most one.

Proof. Induction on the decoded list preserves binary values because a successful accumulator remains one and failure defers to the next one-characteristic. ■

Theorem (`existsList_foldl_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. Induction on the list splits a witness at the head from a witness in the tail while tracking whether success was already present. ■

Theorem (`existsListChar_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. Apply the existential-fold characterization with initial flag zero. ■

Theorem (`fuelTableStep_nth`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Decode the newly built table and use in-range lookup to identify each entry with one application of the body to the corresponding prior-table lookup. ■

Theorem (`fuelTable_succ_nth`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. The successor recursion equation replaces the old table by one table-building step, so the preceding lookup formula applies. ■

Theorem (`fuelTable_zero_nth`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. At zero fuel the table code is zero, whose decoded list is empty, so every lookup returns the default. ■

Theorem (`fuelTable_eq_of_recursion`). Any table family with the same zero table and the same successor lookup recurrence as the fuel table agrees with it at every fuel and bounded index.

Proof. Induction on fuel uses the supplied zero table at the base and the supplied lookup recurrence to identify each successor table extensionally. ■

Theorem (`decodeFuelOkChar_fuelTable_eq`). Lookup in the fuel table equals the fuel-bounded decoding characteristic.

Proof. The fuel table satisfies the same base and successor lookup equations as fuel-bounded decoding, so uniqueness of that recursion identifies them. ■

Theorem (`geTwo_bit`). The displayed binary control recognizes values at least two.

Proof. Separate values below two from successors at least two; truncated subtraction and the one-characteristic give the corresponding binary values. ■

Theorem (`getD_append_cf`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. Split whether the index lies below the first length; concatenated lookup uses the first list there and shifted lookup in the second list otherwise. ■

Theorem (`getD_append_right_cf`). The coded lookup returns the corresponding table entry in range and the prescribed default outside the range.

Proof. An index at least the first length passes through the first list, and lookup continues in the second list at the shifted index. ■

Theorem (`appendListCode_eq`). The coding operation agrees with concatenation or adjoining an entry to a finite list.

Proof. Decode the generated table and split each lookup at the first length; the left and shifted-right formulas agree with concatenation. ■

Theorem (`halfParity_spec`). The recursive binary-digit calculation agrees with ordinary quotient, remainder, or bitwise disjunction.

Proof. Induction on the input follows the two-state parity recursion, alternating the remainder and incrementing the quotient every second step. ■

Theorem (`mapPairStp_eq`). Unpacking a coded map step adjoins the pair of the fixed parameter and current entry to the accumulated list code.

Proof. Unpairing the packed state recovers the fixed parameter, accumulator and current entry, after which one paired entry is adjoined. ■

Theorem (`decodeList_foldl_mapPairStp`). Decoding the map-pair fold gives the reversed mapped input followed by the decoded accumulator.

Proof. Induction on the input list uses the one-step decoding equation and records reversal because each mapped pair is prepended. ■

Theorem (`decodeList_mapPairCode`). Decoding a map-pair code gives the decoded input list with the fixed parameter paired to every entry.

Proof. The coded-fold equation and the map-step decoding formula show by induction that every decoded entry is paired with the fixed parameter. ■

Theorem (`primrec_allListChar`). The numerical function defining allListChar is primitive recursive.

Proof. The allList characteristic construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`RecDecidable2.bForallList`). Universal satisfaction of a recursively decidable binary relation over every entry of a decoded finite list is recursively decidable.

Proof. Encode the finitely many witnesses in one list, then use the decidable list checker to verify each corresponding entry; existential quantification over that witness list gives recursive enumerability. ■

Theorem (`primrec_appendListTabFn`). The numerical function defining appendListTabFn is primitive recursive.

Proof. The appendListTab function construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_appendListCode`). The numerical function defining appendListCode is primitive recursive.

Proof. The appendListCode construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_bForallFn_param`). The numerical function defining bForallFn param is primitive recursive.

Proof. The bForall function param construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_codeBound`). The numerical function defining codeBound is primitive recursive.

Proof. The codeBound construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_decodeFuelOkChar`). The numerical function defining decodeFuelOkChar is primitive recursive.

Proof. The decodeFuelOk characteristic construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_decodeFuelOkCharLookup`). The numerical function defining decodeFuelOkCharLookup is primitive recursive.

Proof. The decodeFuelOk characteristicLookup construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_existsListStp`). The numerical function defining existsListStp is primitive recursive.

Proof. The existsList step construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_existsListChar`). The numerical function defining existsListChar is primitive recursive.

Proof. The existsList characteristic construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`RecDecidable2.bExistsList`). Existence of an entry in a decoded finite list satisfying a recursively decidable binary relation is recursively decidable.

Proof. A bounded primitive recursion accumulates the disjunction of the characteristic values below the bound, giving a recursive decision procedure for bounded existence. ■

Theorem (`primrec_fuelTable`). The numerical function defining fuelTable is primitive recursive.

Proof. The fuelTable construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_decodeFuelOkChar2`). The numerical function defining decodeFuelOkChar2 is primitive recursive.

Proof. The decodeFuelOk characteristic2 construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_halfParity`). The numerical function defining halfParity is primitive recursive.

Proof. The halfParity construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_div2`). The numerical function defining div2 is primitive recursive.

Proof. The div2 construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_ite`). The numerical function defining ite is primitive recursive.

Proof. The ite construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_mapPairStp`). The numerical function defining mapPairStp is primitive recursive.

Proof. The mapPair step construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_mapPairCode`). The numerical function defining mapPairCode is primitive recursive.

Proof. The mapPairCode construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`REPred.forall_mem_decodeList2`). If a binary relation is recursively enumerable, then requiring it between a fixed input and every member of a decoded finite list is recursively enumerable.

Proof. Pair the fixed outer argument into the binary relation, apply finite-list universal closure, and use primitive-recursive reassociation of the paired inputs. ■

Theorem (`primrec_max`). The numerical function defining max is primitive recursive.

Proof. The max construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_max_one`). The numerical function defining max one is primitive recursive.

Proof. The max one construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_mod2`). The numerical function defining mod2 is primitive recursive.

Proof. The mod2 construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_lowOr`). The numerical function defining lowOr is primitive recursive.

Proof. The lowOr construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_lorStep`). The numerical function defining lorStep is primitive recursive.

Proof. The lorStep construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_myLor`). The numerical function defining myLor is primitive recursive.

Proof. The myLor construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`recDecidable_of_forall`). An everywhere-true predicate on natural numbers is recursively decidable.

Proof. The constant-one characteristic is primitive recursive and accepts every input, matching the hypothesis pointwise. ■

Theorem (`rePred_of_forall`). An everywhere-true predicate on natural numbers is recursively enumerable.

Proof. First decide it by the constant-one characteristic, then use the standard inclusion of decidable predicates among recursively enumerable predicates. ■

Theorem (`recDecidable2_of_forall`). An everywhere-true binary predicate on natural numbers is recursively decidable.

Proof. After pairing the two arguments, the predicate remains universally true and is decided by the constant-one characteristic. ■

Theorem (`recPow_eq`). The primitive recursion that repeatedly multiplies by the base computes natural-number exponentiation.

Proof. Induction on the exponent uses the zero exponent equation and one further multiplication in the successor case. ■

Theorem (`primrec_pow`). The numerical function defining pow is primitive recursive.

Proof. The pow construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_pow2`). The numerical function defining pow2 is primitive recursive.

Proof. The pow2 construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`primrec_two_pow`). The numerical function defining two pow is primitive recursive.

Proof. The two pow construction is assembled from primitive-recursive projections, constants, pairing, composition and its displayed bounded fold or primitive recursion. ■

Theorem (`selectFn_isOne_one_sub_sigma`). For binary inputs, the nested selector returns zero exactly in the exceptional control configuration and one otherwise.

Proof. The binary input sum is zero, one or at least two; evaluating truncated subtraction and the one-characteristic in these cases gives the selected value. ■

4.8.3 Computable presentation

A computable presentation of a neighbourhood system: an enumeration of the neighbourhoods for which intersection and consistency are recursively decidable.

Definition (`ComputablePresentation`). A computable presentation enumerates all neighbourhoods, decides equality with intersections and consistency of pairs, computes intersections whenever they are consistent, and supplies an index for the master neighbourhood.

Definition (`NeighborhoodSystem.IsEffectivelyGiven`). A neighbourhood system is effectively given when it admits a computable presentation.

Definition (`ComputablePresentation.inclShuffle`). This reindexing sends a pair of indices to the triple that compares the first neighbourhood intersected with the second against the first.

Definition (`ComputablePresentation.reindexInvolutive`). An involutive primitive-recursive permutation of indices transports a computable presentation to an equivalent presentation.

Definition (`ComputablePresentation.swapPair`). This operation exchanges the two components of a paired natural number.

Definition (`unitPresentation`). The one-point neighbourhood system is presented by the constant enumeration of its unique neighbourhood.

Theorem (`ComputablePresentation.primrec_inclShuffle`). The reindexing used to reduce inclusion to intersection equality is primitive recursive.

Proof. The two coordinate projections are primitive recursive, and pairing them first with one another and then with the repeated first coordinate preserves primitive recursiveness. ■

Theorem (`ComputablePresentation.primrec_swapPair`). Exchanging the components of a paired natural number is primitive recursive.

Proof. The first and second projections are primitive recursive, and pairing them in reverse order gives the required permutation. ■

Theorem (`ComputablePresentation.incl_computable`). Inclusion between two enumerated neighbourhoods is recursively decidable.

Proof. A neighbourhood is contained in another exactly when intersecting it with the latter returns the former; the shuffled triple is therefore decided by the presentation's intersection-equality test. ■

Theorem (`ComputablePresentation.eq_computable`). Equality between two enumerated neighbourhoods is recursively decidable.

Proof. Two neighbourhoods are equal exactly when each contains the other, so conjunction of the two decidable inclusion tests decides equality. ■

Theorem (`unitSys_isEffectivelyGiven`). The one-point neighbourhood system is effectively given.

Proof. The constant enumeration by the whole one-point set is surjective; every intersection and consistency question is automatically true, and the constant index zero names both intersections and the master neighbourhood. ■

4.8.4 Definition 7.1 — computable presentation

DEFINITION 7.1. A neighbourhood system D has a *computable presentation* provided we can write

$$D = \{X_n \mid n \in N\},$$

where the following two relations

(i) $X_n \cap X_m = X_k$; and

(ii) $\exists k \in N.\, X_k \subseteq X_n$ and $X_k \subseteq X_m$

are recursively decidable (in integer indices n, m, k and in n, m, respectively). □

More strictly the sequence,

$$\langle X_n \rangle_{n=0}^{\infty},$$

is the presentation. Even more strictly, when it is required to cope with infinitely many domains at a time, it would be necessary to give the actual Gödel numbers of the recursive relations (i) and (ii) (rather than just saying there exists some way of showing them to be recursively decidable).

The intuitive idea of 7.1 is that the system is effectively given if you know how to do elementary "calculations" with neighbourhoods. The basic calculations are the forming of intersections. The neighbourhoods have to be laid out in a systematic way; and, if we are asked for an intersection of two given neighbourhoods, we have to be able to locate it in the standard sequence. Relation (ii) is the *consistency condition* , which is the necessary and sufficient condition for the intersection to exist in D. When (ii) is true, therefore, we have only to try $k = 0, 1, 2, \ldots$ until we discover that we have found the intersection. We are

assuming that these basic decisions can be carried out in "finite time". Note that the obvious biconditional,

$$X_n \subseteq X_m \text{ iff } X_n \cap X_m = X_n,$$

assures us that the inclusion relation between neighbourhoods is itself decidable in terms of the indices. So in (ii) if k exists, *then* it (or the first one) can indeed be found in finite time. The rub is that if it *does not exist*, no finite number of inclusion checks will determine that fact. That is why we have to *assume* that (ii) is always decidable. The information contained in (ii) is a fundamental part of the neighbourhood structure. (An axiomatic characterization of neighbourhood structures is given in Exercise 7.13, which may make clearer what we are assuming and what a presentation is.)

The development is with the recursive predicates and computable presentation peers.

Theorem (`definition_71`). A neighbourhood system is effectively given precisely when it has a computable presentation, and for any such presentation inclusion and equality of enumerated neighbourhoods are recursively decidable.

Proof. The equivalence is the definition of effective givenness. Inclusion and equality reduce to the decidable intersection relation of the presentation. ■

4.8.5 Computable map

Computable elements and computable approximable maps on effectively given domains.

Definition (`ComputableElement`). An element is computable relative to a presentation when the set of indices of its neighbourhoods is recursively enumerable.

Definition (`ComputableMap`). An approximable map is computable relative to two presentations when its relation on enumerated neighbourhoods is recursively enumerable.

4.8.6 Definition 7.2 — computable mapping

DEFINITION 7.2. Given two recursively presented domains,

$$\mathcal{D} = \{X_n \mid n \in \mathbf{N}\} \text{ and } E = \{Y_m \mid m \in \mathbf{N}\},$$

an approximable mapping $f : \mathcal{D} \to E$ is said to be *computable* iff the relation

$$X_n f Y_m$$

is recursively enumerable in n and m. □

The question to ask first is why "recursively enumerable" rather than "recursive" (= "recursively decidable")? The answer will become clear when we let $\mathcal{D}$ degenerate to the one-element domain, $\mathcal{D} = \{\Delta\}$. Then what we are considering is merely a single element

$$y = f(\{\Delta\}) \in |E|.$$

Therefore, 7.2 incorporates the notion of a *computable element* of a domain. And the condition reduces to the statement that the filter $y \in |E|$ is such that the set

$$\{m \in \mathbf{N} \mid Y_m \in y\}$$

is a recursively enumerable set of integers. The point is that the elements of $|E|$ are finite or infinite. If y were finite, the set of indices above would indeed be recursive in view of

our assumptions on E. But an infinite element can in general only be approximated "a little at a time". We cannot expect to know the whole story of its approximations in a flash. What it means to be recursively enumerable is that there is a primitive recursive function (hence, a total function), $r : \mathbf{N} \to \mathbf{N}$, such that

$$y = \{Y_{r(i)} \mid i \in \mathbf{N}\}.$$

That is to say, *all* the approximations to y can eventually be listed. In the case of the mapping f we could write

$$f = \{(X_{s(i)}, Y_{r(i)}) \mid i \in \mathbf{N}\},$$

for a suitable pair of primitive recursive functions s and r.

Definitions 7.1 and 7.2 may very well irritate the person hearing them for the first time: instead of explaining computability in direct terms, the whole question is thrown into the lap of recursion theory! There are several answers. "You have to start somewhere" is one thing I always say. Recursion on the integers is a well-understood theory, and we shall not need the refined parts of the development, fortunately. In any case, our definitions apply to *many* domains of quite different structure, not just to the domain $\mathbf{N}$. And the next step we shall take is to show how to build up computable functions (and also effectively given domains) from simpler ones. Thus, often it will not be necessary to go back to the seemingly over-precise definitions involving the indices but to appeal to some broad general principles.

The development is with the computable map peer.

Theorem (`definition_72`). An approximable map between computably presented domains is computable exactly when its neighbourhood relation is recursively enumerable in the two indices, and an element is computable exactly when the indices of neighbourhoods it contains are recursively enumerable.

Proof. Both directions are the defining recursively enumerable predicates of a computable map and a computable element. ■

4.8.7 Computable maps form a category

Identity, composition, application, and principal elements stay inside the computable maps and computable elements.

Theorem (`apply_isComputableElement`). Applying a computable approximable map to a computable element yields a computable element.

Proof. The required relation is obtained from recursively enumerable or decidable index relations by pairing, composition, conjunction, and projection. ■

Theorem (`comp_isComputable`). The composite of two computable approximable maps is computable.

Proof. The required relation is obtained from recursively enumerable or decidable index relations by pairing, composition, conjunction, and projection. ■

Theorem (`idMap_isComputable`). The identity approximable map of an effectively presented system is computable.

Proof. The required relation is obtained from recursively enumerable or decidable index relations by pairing, composition, conjunction, and projection. ■

Theorem (`principal_isComputableElement`). Every principal element generated by an enumerated neighbourhood is computable.

Proof. The required relation is obtained from recursively enumerable or decidable index relations by pairing, composition, conjunction, and projection. ■

4.8.8 Proposition 7.3 — computable maps form a category

PROPOSITION 7.3. The identity map on an effectively given domain is computable; the composition of computable mappings on effectively given domains is again computable. □

The proofs for 7.3 are so trivial they are hardly worth an exercise. Note the immediate and useful consequence: if $f : D \to E$ is computable and $x \in |D|$ is computable, then $f(x) \in |E|$ is also computable.

The next result is, however, worth working out even though it is quite easy.

The development is with the computable maps form a category peer.

Theorem (`proposition_73`). Application of a computable map to a computable element is computable; composition of computable maps is computable; the identity map of an effectively given domain is computable; and each principal neighbourhood of a presentation is a computable element.

Proof. The four facts of the computable-category peer. ■

4.8.9 Effective sum

The sum of effectively given neighbourhood systems is effectively given, and the sum combinators are computable.

Definition (`sumEnum`). The sum enumeration uses tag zero for left neighbourhoods, tag one for right neighbourhoods, and every other tag for the master neighbourhood.

Theorem (`sumEnum_zero`). An index tagged by zero denotes the corresponding left neighbourhood.

Proof. The outer tag test takes its zero branch, which returns the left injection at the second component of the index. ■

Theorem (`sumEnum_one`). An index tagged by one denotes the corresponding right neighbourhood.

Proof. The zero branch is excluded and the next tag test takes its one branch, returning the right injection at the second component. ■

Theorem (`inj0_eq_iff`). Two left-injected neighbourhoods are equal exactly when their underlying left neighbourhoods are equal.

Proof. Injectivity of the corresponding tagged embedding gives the forward implication, and substitution gives the converse. ■

Theorem (`inj0_eq_inj1_elim`). A nonempty left-injected neighbourhood cannot equal a right-injected neighbourhood.

Proof. Choose an element of the assumed nonempty summand; its left and right tags cannot coincide, contradicting the proposed equality. ■

Theorem (`inj0_ne_inj1_of_nonempty`). A left-injected neighbourhood cannot equal a nonempty right-injected neighbourhood.

Proof. Choose an element of the assumed nonempty summand; its left and right tags cannot coincide, contradicting the proposed equality. ■

Theorem (`inj0_ne_sumMaster`). No left-injected neighbourhood equals the master neighbourhood of the sum.

Proof. The sum master contains the distinguished untagged point, whereas an injected summand contains only tagged points. ■

Theorem (`inj1_eq_iff`). Two right-injected neighbourhoods are equal exactly when their underlying right neighbourhoods are equal.

Proof. Injectivity of the corresponding tagged embedding gives the forward implication, and substitution gives the converse. ■

Theorem (`inj1_ne_sumMaster`). No right-injected neighbourhood equals the master neighbourhood of the sum.

Proof. The sum master contains the distinguished untagged point, whereas an injected summand contains only tagged points. ■

Theorem (`recDec_setEq0`). Equality of left neighbourhoods whose indices are computed primitively is recursively decidable.

Proof. Set equality is mutual inclusion, so compose the presentation's decidable inclusion relation with the two primitive-recursive index functions in both orders and conjoin the results. ■

Theorem (`recDec_setEq1`). Equality of right neighbourhoods whose indices are computed primitively is recursively decidable.

Proof. Set equality is mutual inclusion, so compose the presentation's decidable inclusion relation with the two primitive-recursive index functions in both orders and conjoin the results. ■

Theorem (`sumEnum_master`). Every index tagged by a number other than zero or one denotes the master neighbourhood of the sum.

Proof. Both distinguished tag tests fail, so the remaining branch is the sum master neighbourhood. ■

Theorem (`sumEnum_mem`). Every set produced by the tagged sum enumeration is a sum neighbourhood.

Proof. The three tag cases are respectively a valid left neighbourhood, a valid right neighbourhood, and the master neighbourhood, all admitted by the definition of the sum system. ■

Theorem (`sumEnum_nonempty`). Every neighbourhood produced by the tagged sum enumeration is nonempty.

Proof. Inspect the tag: a left or right neighbourhood is nonempty by the corresponding factor hypothesis, while the master case contains the distinguished untagged point. ■

Theorem (`sumEnum_subset_sumMaster`). Every neighbourhood in the sum enumeration is contained in the master neighbourhood.

Proof. In each tag case the injected factor neighbourhood lies in the sum master; the remaining tag already denotes the master itself. ■

Theorem (`sumEnum_inter_sumMaster`). Intersecting an enumerated sum neighbourhood with the master neighbourhood leaves it unchanged.

Proof. Every enumerated sum neighbourhood is contained in the master neighbourhood, so the left-hand absorption law for intersection applies. ■

Theorem (`sumMaster_inter_sumEnum`). Intersecting the master neighbourhood with an enumerated sum neighbourhood leaves that neighbourhood unchanged.

Proof. Every enumerated sum neighbourhood lies inside the master neighbourhood, so the right-hand absorption law for intersection applies. ■

Theorem (`tag_trichotomy`). Every natural-number tag is zero, one, or distinct from both zero and one.

Proof. Decidable equality first separates zero; in the remaining case it separates one, leaving a tag unequal to both. ■

Theorem (`sumEnum_eq_iff`). Two tagged sum indices denote the same neighbourhood exactly when both are master tags, or both have the same summand tag and equal underlying factor neighbourhoods.

Proof. The nine combinations of left, right, and master tags are disjoint: equal tags reduce by injectivity to equality in one factor, and two master tags are automatically equal. ■

Theorem (`eqSEdec`). Equality between two neighbourhoods in the tagged sum enumeration is recursively decidable.

Proof. Decide the tags of both indices. Master tags agree with one another, matching left or right tags invoke decidable equality in that factor, and all mixed tags are unequal. ■

Definition (`sumPresentation`). The tagged enumeration of left, right, and master neighbourhoods forms a computable presentation of the sum.

Theorem (`sum_isEffectivelyGiven`). The sum neighbourhood system is effectively given.

Proof. Choose computable presentations of the two factors; their tagged sum presentation supplies a computable presentation of the sum. ■

Theorem (`sumPresentation_X`). The neighbourhood family of the sum presentation is exactly the tagged sum enumeration.

Proof. This is the corresponding defining equation after substituting the displayed arguments. ■

Theorem (`inMap0_isComputable`). The left injection into an effectively presented sum is computable.

Proof. Split the target index into left, right and master tags. The left case is exactly decidable inclusion in the first factor, the right case is impossible by nonemptiness, and the master case always holds. ■

Theorem (`inMap1_isComputable`). The right injection into an effectively presented sum is computable.

Proof. Split the target index into left, right and master tags. The right case is exactly decidable inclusion in the second factor, the left case is impossible by nonemptiness, and the master case always holds. ■

Theorem (`outMap0_isComputable`). The map extracting the left component of an effectively presented sum is computable.

Proof. Choose an index for the first master neighbourhood. A left-tagged source reduces to factor inclusion, while right-tagged and master sources both reduce to inclusion of that chosen master index. ■

Theorem (`outMap1_isComputable`). The map extracting the right component of an effectively presented sum is computable.

Proof. Choose an index for the second master neighbourhood. A right-tagged source reduces to factor inclusion, while left-tagged and master sources both reduce to inclusion of that chosen master index. ■

Theorem (`sumMap_isComputable`). The map induced componentwise by two computable maps between sums is computable.

Proof. The target master case is automatic. Matching left tags use the recursively enumerable relation for the first component map, matching right tags use that for the second, and all mismatched nonmaster tags are excluded by disjointness and nonemptiness. ■

4.8.10 Effective product

The product of effectively given neighbourhood systems is effectively given, and the product combinators are computable.

Definition (`prodEnum`). The product enumeration pairs an index from each factor and returns the corresponding product neighbourhood.

Theorem (`prodEnum_apply`). The neighbourhood at a paired product index is the product of the two neighbourhoods at its component indices.

Proof. Both product coordinates reduce to the corresponding facts in the two factor presentations. ■

Theorem (`prodNbhd_eq_iff`). Two product neighbourhoods are equal exactly when their left components and their right components are respectively equal.

Proof. Both product coordinates reduce to the corresponding facts in the two factor presentations. ■

Definition (`prodPresentation`). Pairing the two factor enumerations gives a computable presentation of the product neighbourhood system.

Theorem (`prodPresentation_X`). The product presentation enumerates the product of the neighbourhoods named by the two components of an index.

Proof. Both product coordinates reduce to the corresponding facts in the two factor presentations. ■

Theorem (`paired_isComputable`). Pairing two computable approximable maps with common source gives a computable map into the product.

Proof. The required relation is obtained from recursively enumerable or decidable index relations by pairing, composition, conjunction, and projection. ■

Theorem (`prod_isEffectivelyGiven`). The product of two effectively given neighbourhood systems is effectively given.

Proof. Both product coordinates reduce to the corresponding facts in the two factor presentations. ■

Theorem (`proj0_isComputable`). The first projection from an effectively presented product is computable.

Proof. The required relation is obtained from recursively enumerable or decidable index relations by pairing, composition, conjunction, and projection. ■

Theorem (`proj1_isComputable`). The second projection from an effectively presented product is computable.

Proof. The required relation is obtained from recursively enumerable or decidable index relations by pairing, composition, conjunction, and projection. ■

Theorem (`prodMap_isComputable`). The product of two computable approximable maps is computable.

Proof. The required relation is obtained from recursively enumerable or decidable index relations by pairing, composition, conjunction, and projection. ■

4.8.11 Theorem 7.4 — sum and product effective

THEOREM 7.4. If $\mathcal{D}_0$ and $\mathcal{D}_1$ are effectively given, then so are $(\mathcal{D}_0 + \mathcal{D}_1)$ and $(\mathcal{D}_0 \times \mathcal{D}_1)$.

Moreover the combinators in_i and out_i and proj_i^2 are all computable; further, if f and g are computable maps, then so are $f + g$ and $f \times g$.

Proof: Let the computable presentations be given as:

$$\mathcal{D}_i = \{X_n^i \mid n \in \mathbf{N}\}.$$

We can assume that the sets of tokens Δ_0 and Δ_1 are disjoint and $\emptyset \notin \mathcal{D}_i$. Then the construction of the sum is just

$$\mathcal{D}_0 + \mathcal{D}_1 = \{\Delta_0 \cup \Delta_1\} \cup \mathcal{D}_0 \cup \mathcal{D}_1.$$

As an enumeration we define for $n \in \mathbf{N}$:

$$Z_0 = \Delta_0 \cup \Delta_1 \; ; \; Z_{2n+1} = X_n^0 \; ; \; Z_{2n+2} = X_n^1 \; .$$

We leave as an exercise the check of 7.1(i)–(ii).

For the product we want:

$$\mathcal{D}_0 \times \mathcal{D}_1 = \{X^0_n \cup X^1_m \mid n, m \in \mathbf{N}\}.$$

What we then need are recursive functions $p : \mathbf{N} \to \mathbf{N}$, $q : \mathbf{N} \to \mathbf{N}$, and $r : \mathbf{N} \times \mathbf{N} \to \mathbf{N}$ where for $m, n, k \in \mathbf{N}$ we have:

$$p(r(n, m)) = n \text{ and } q(r(n, m)) = m, \text{ and } r(p(k), q(k)) = k.$$

Thus r is a "one-one pairing function"; there are many ways to find such functions (see Exercise 5.13). We can then define for $k \in \mathbf{N}$:

$$W_k = X^0_{p(k)} \cup X^1_{q(k)} .$$

Again we leave as an exercise the check that this provides a computable presentation of $\mathcal{D}_0 \times \mathcal{D}_1$.

As for the combinators, the neighbourhood relations have to be worked out in terms of the indices. For example

$$X^0_n \text{ in}_0 \ Z_m \text{ iff either } m = 0 \text{ or for some } k$$

$$m = 2k + 1 \text{ and } X^0_n \subseteq X^0_k .$$

and

$$W_k \text{ proj}^2_1 \ X^1_m \text{ iff } X^1_{q(k)} \subseteq X^1_m .$$

The reader needs to check that these are recursively enumerable

Relations in the indices. For this purpose it may be convenient to recall some closure properties of these relations: taking conjunctions, disjunctions, substituting recursive functions, applying an existential quantifier to the front. □

Products give us a way of providing an immediate meaning to the notion of a computable function of several variables. Note that the proof of 3.7 is "effective" and shows that substitution of computable functions of several variables into each other always gives computable functions. We turn next to the function spaces.

The development is with the effective sum and effective product peers.

Theorem (`theorem_74`). If two neighbourhood systems are effectively given, then so are their sum and their product. The injections, the projections, and the sum and product of computable maps are computable.

Proof. By the effective sum and the effective product. ■

4.8.12 Function-space presentation

The function space of effectively given systems is effectively given, and evaluation and currying are computable.

Definition (`interList`). Starting from a base set, this operation intersects all sets in a finite list.

Theorem (`interList_nil`). Intersecting no listed sets leaves the base set.

Proof. The empty list contributes no intersections, so the recursive definition returns the base set. ■

Definition (`funPair`). A paired index denotes the pair consisting of the corresponding source and target neighbourhoods.

Theorem (`funPair_fst`). The first component of a paired index is the source neighbourhood named by its first numerical component.

Proof. The first projection of the interpreted pair is the source neighbourhood indexed by the first unpaired component. ■

Theorem (`funPair_snd`). The second component of a paired index is the target neighbourhood named by its second numerical component.

Proof. The second projection of the interpreted pair is the target neighbourhood indexed by the second unpaired component. ■

Definition (`bitSelect`). A natural number is read as a bit mask selecting a sublist from a given finite list.

Theorem (`bitSelect_nil`). Every mask selects the empty sublist from the empty list.

Proof. There are no entries to inspect, so every mask selects the empty list. ■

Theorem (`andFoldl_eq_one_iff`). The characteristic value is one exactly when every finite condition encoded in its arguments holds.

Proof. Induction on the list uses the binary bound on the accumulator; each update is one exactly when the old flag and the current test are both one. ■

Theorem (`andFoldl_one`). Starting with success, the finite conjunction fold returns one exactly when every listed value is one.

Proof. Specializing the preceding fold characterization to initial flag one removes the redundant initial conjunct. ■

Definition (`appendStep`). This operation adjoins one natural number to the front of an accumulated list code.

Definition (`appendStp`). This packed fold step adjoins the current entry to an accumulated list code.

Definition (`appendCode`). This operation combines two list codes by folding the entries of one into the other.

Theorem (`appendStp_eq`). The coding operation agrees with concatenation or adjoining an entry to a finite list.

Proof. Unpairing the packed entry and accumulator recovers both arguments of the adjoining operation. ■

Definition (`botMap`). The least approximable map relates every source neighbourhood only as forced by the master target neighbourhood.

Theorem (`botMap_rel`). The least approximable map relates a source neighbourhood to a target neighbourhood exactly when both are valid and the master target neighbourhood is contained in the latter.

Proof. The least map generated by an empty constraint list contains exactly the mandatory master-target relation, together with validity of both neighbourhoods. ■

Definition (`condSet`). This set consists of the points in a base target neighbourhood satisfying every consequent whose antecedent contains a fixed source neighbourhood.

Theorem (`condSet_nil`). With no constraints, the conditional set is the initial target set.

Proof. Set extensionality identifies both sides pointwise: each asks for membership in the base and in every consequent whose antecedent contains the fixed neighbourhood. ■

Theorem (`condSet_subset`). Every conditional intersection is contained in its initial target neighbourhood.

Proof. Membership in the conditional set includes membership in the initial target set as its first conjunct, which gives the inclusion. ■

Definition (`consPairChar`). This zero-one characteristic tests whether two enumerated function-space neighbourhoods have a consistent intersection.

Definition (`consUpd`). This state update scans a selected sublist, intersects the chosen neighbourhood indices, and records whether each required intersection remains consistent.

Definition (`consStp`). This packed fold step applies the consistency update to one coded entry.

Definition (`consCharAt`). This characteristic tests whether the neighbourhoods selected by a bit mask have a consistent finite intersection.

Theorem (`decodeList_appendStep`). Decoding an adjoining step gives the new entry followed by the decoded accumulator.

Proof. The successor decoding equation unpairs the predecessor into the newly adjoined head and the former accumulator code. ■

Theorem (`decodeList_encodeList`). Decoding the code of a finite list recovers the list.

Proof. Induction on the list or code uses the successor coding equation and the fact that unpairing a freshly paired head and tail recovers both components. ■

Theorem (`decodeList_foldl_appendStp`). Decoding an adjoining fold gives the reverse of the folded entries followed by the decoded accumulator.

Proof. Induction on the folded list uses the adjoining equation at each head; because entries are prepended, the processed prefix appears in reverse order. ■

Theorem (`decodeList_appendCode`). Decoding the combined code gives the reversed second decoded list followed by the first.

Proof. The coded-fold equation and the preceding decoding formula identify the result as the reversed second list followed by the first. ■

Definition (`funImpChar`). This characteristic represents the implication from consistency of selected antecedents to consistency of selected consequents.

Definition (`funConsChar`). This bounded universal characteristic tests consistency of a finite family of step constraints over all selected subfamilies.

Definition (`funListOf`). A list of paired indices is interpreted as a list of source-target neighbourhood pairs.

Definition (`Xenum`). A consistent code denotes its finite step-function neighbourhood; an inconsistent code denotes the master function-space neighbourhood.

Theorem (`Xenum_neg`). A code rejected by the consistency characteristic denotes the whole function space.

Proof. A failed consistency test takes the second branch of the enumeration, which is the whole function space. ■

Theorem (`Xenum_pos`). A code accepted by the consistency characteristic denotes the finite step-function neighbourhood determined by its decoded constraints.

Proof. A successful consistency test takes the first branch, the step neighbourhood generated by the decoded constraints. ■

Theorem (`funListOf_cons`). Interpreting a nonempty index list gives the interpreted head pair followed by the interpreted tail.

Proof. Mapping interpreted paired indices over a cons list preserves its head and maps the tail. ■

Theorem (`exists_funListOf`). Every finite list of valid source-target neighbourhood pairs is represented by a list of paired presentation indices.

Proof. Induction on the finite pair list chooses source and target indices by surjectivity of the two presentations, pairs those indices, and applies the induction hypothesis to the tail. ■

Theorem (`funListOf_valid`). Every pair represented by a list of paired indices consists of valid source and target neighbourhoods.

Proof. Every list entry comes from a paired index, and each coordinate enumeration always names a valid neighbourhood. ■

Theorem (`Xenum_mem`). Every set produced by the function-space enumeration is a function-space neighbourhood.

Proof. In the successful case, consistency supplies nonemptiness of a valid finite step neighbourhood; in the failed case, the whole function space is its master neighbourhood. ■

Theorem (`Xenum_nonempty`). Every neighbourhood in the function-space enumeration is nonempty.

Proof. Every enumerated set is a neighbourhood, and nonemptiness is part of the neighbourhood axiom in the function-space system. ■

Definition (`idxchain`). This index is obtained by successively intersecting a finite list of neighbourhood indices, beginning with the master index.

Definition (`interFrom`). This operation successively intersects a starting set with the neighbourhoods named by a list of indices.

Definition (`interIdx`). This index denotes the intersection of two enumerated function-space neighbourhoods whenever both are proper, and otherwise selects the proper one.

Definition (`interYsStp`). This fold step intersects a target accumulator with a consequent exactly when the fixed antecedent is contained in the current antecedent.

Definition (`interYsIdx`). This operation computes an index for the intersection of all consequents applicable to a fixed antecedent.

Theorem (`mem_condSet`). A point belongs to the conditional set exactly when it lies in the base and in every consequent whose antecedent contains the fixed source neighbourhood.

Proof. This is the membership condition defining the conditional set: membership in the base together with every applicable consequent. ■

Theorem (`condSet_cons_neg`). A constraint whose antecedent does not contain the fixed source neighbourhood contributes no condition to the conditional intersection.

Proof. The head implication has a false antecedent, hence imposes no condition; the remaining universal conditions are exactly those from the tail. ■

Theorem (`condSet_cons_pos`). A constraint whose antecedent contains the fixed source neighbourhood contributes intersection with its consequent.

Proof. When the fixed antecedent is contained in the head antecedent, the head condition requires membership in its consequent, producing one additional intersection before processing the tail. ■

Theorem (`condFoldl_spec`). Folding the computable intersection indices yields an index for the conditional intersection determined by the finite constraint list.

Proof. Induction on the constraint list skips a head when inclusion fails and otherwise computes the intersection with its consequent; neighbourhood consistency licenses the presentation's intersection index. ■

Theorem (`condSet_eq_interYs`). Starting from the master target neighbourhood, the conditional intersection equals the intersection of all consequents applicable to the fixed antecedent.

Proof. Set extensionality identifies both sides pointwise: each asks for membership in the base and in every consequent whose antecedent contains the fixed neighbourhood. ■

Theorem (`primrec_appendCode`). The numerical function defining appendCode is primitive recursive.

Proof. The append code function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`primrec_consPairChar`). The numerical function defining consPairChar is primitive recursive.

Proof. The cons pair characteristic function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`primrec_interIdx`). The numerical function defining interIdx is primitive recursive.

Proof. The inter idx function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`primrec_interYsStp`). The numerical function defining interYsStp is primitive recursive.

Proof. The inter ys step function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`primrec_interYsIdx`). The numerical function defining interYsIdx is primitive recursive.

Proof. The inter ys idx function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`rel_interYs_funList`). Every map satisfying a finite list of step constraints relates each source neighbourhood to the intersection of all applicable consequents.

Proof. Induction on the constraint list ignores heads whose antecedent does not contain the chosen source and otherwise combines the head relation with the induction hypothesis by target intersection. ■

Theorem (`interYs_funList_mem_of_nonempty`). If a finite step-function neighbourhood is nonempty, then its intersection of applicable consequents is a target neighbourhood.

Proof. The inclusion characteristic selects exactly the applicable consequents, and induction over the decoded list shows that the computed presentation intersections denote their set-theoretic intersection. ■

Theorem (`selectFn_isOne`). Selection controlled by the characteristic of one chooses the first value exactly when the tested value is one.

Proof. Substitution of the control value into the arithmetic definition cancels one summand and leaves the selected argument. ■

Theorem (`interYsIdx_spec`). The computed target index denotes exactly the intersection of all consequents applicable to the chosen antecedent.

Proof. The inclusion characteristic selects exactly the applicable consequents, and induction over the decoded list shows that the computed presentation intersections denote their set-theoretic intersection. ■

Theorem (`selectFn_mul_iff`). Selection with default zero has value one exactly when both its control and selected value are one.

Proof. The selector with zero default is the product of its two inputs, and a product of natural numbers is one precisely when both factors are one. ■

Theorem (`stepFun_funListOf_appendCode`). The finite step neighbourhood represented by the combined code is the intersection of the neighbourhoods represented by the two original codes.

Proof. Interpretation is list mapping by paired indices, and mapping distributes over concatenation. ■

Theorem (`Xenum_inter_eq`). Whenever the intersection is nonempty, the computed intersection index denotes exactly the intersection of the two enumerated function-space neighbourhoods.

Proof. Split on the two consistency bits. If both codes are proper, concatenating their constraint lists represents intersection; if either is improper, its neighbourhood is the whole space and intersection returns the other. ■

Theorem (`consPairChar_spec`). The pair-consistency characteristic is one exactly when some enumerated function-space neighbourhood is contained in the intersection.

Proof. Existence of such a refinement is equivalent to nonemptiness of the intersection. When nonempty, the computed intersection index is a witness; conversely every enumerated refinement is itself nonempty. ■

Theorem (`stepFun_funListOf_eq_univ_iff`). A finite step-function neighbourhood is the whole function space exactly when every listed consequent is the master neighbourhood.

Proof. Testing the alleged equality on the least approximable map forces each consequent to contain the master and hence equal it; conversely, master consequents are satisfied by every map through its mandatory master relation. ■

Theorem (`stepFun_funListOf_subset_iff`). Inclusion of the two finite step-function neighbourhoods is equivalent to containment of every required consequent by the intersection generated from the first family.

Proof. The least map generated by the first constraints supplies necessity; conversely, each map satisfying those constraints relates an antecedent to their applicable-consequent intersection, and monotonicity yields every constraint in the second family. ■

Definition (`subStp`). This fold step preserves a success flag precisely when the computed applicable-consequent intersection is contained in the current consequent.

Theorem (`primrec_subStp`). The numerical function defining subStp is primitive recursive.

Proof. The sub step function is built from primitive-recursive projections, constants, pairing and composition. ■

Definition (`subChar`). This characteristic tests inclusion between two finite step-function neighbourhoods.

Theorem (`primrec_subChar`). The numerical function defining subChar is primitive recursive.

Proof. The sub characteristic function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`subChar_spec`). The inclusion characteristic has value one exactly when the first finite step-function neighbourhood is contained in the second.

Proof. The least map generated by the first constraints supplies necessity; conversely, each map satisfying those constraints relates an antecedent to their applicable-consequent intersection, and monotonicity yields every constraint in the second family. ■

Definition (`trivStp`). This fold step preserves a success flag precisely when the current consequent is the master neighbourhood.

Theorem (`primrec_trivStp`). The numerical function defining trivStp is primitive recursive.

Proof. The triv step function is built from primitive-recursive projections, constants, pairing and composition. ■

Definition (`trivialChar`). This characteristic tests whether a finite step-function neighbourhood is the entire function space.

Definition (`eqEnumChar`). This characteristic tests equality of two enumerated function-space neighbourhoods, treating inconsistent codes as the master neighbourhood.

Definition (`interEqChar`). This characteristic tests whether one enumerated function-space neighbourhood is the intersection of two others.

Theorem (`primrec_trivialChar`). The numerical function defining trivialChar is primitive recursive.

Proof. The trivial characteristic function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`primrec_eqEnumChar`). The numerical function defining eqEnumChar is primitive recursive.

Proof. The equality enum characteristic function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`primrec_interEqChar`). The numerical function defining interEqChar is primitive recursive.

Proof. The interequality characteristic function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`trivialChar_spec`). The triviality characteristic has value one exactly when the finite step-function neighbourhood is the whole function space.

Proof. The finite conjunction accepts precisely when every consequent in the decoded constraints equals the master neighbourhood, which is exactly the criterion for the step neighbourhood to be the whole function space. ■

Theorem (`eqEnumChar_spec`). The equality characteristic has value one exactly when the two enumerated function-space neighbourhoods are equal.

Proof. Separate the four consistency cases. Two proper neighbourhoods are equal exactly by mutual inclusion; a proper and an improper code are equal exactly when the proper one is the whole space; two improper codes both denote the whole space. ■

Theorem (`interEqChar_spec`). The intersection-equality characteristic has value one exactly when the first two enumerated neighbourhoods intersect to the third.

Proof. The consistency test first guarantees that the computed intersection index denotes the actual intersection, and the equality characteristic then compares that neighbourhood with the third one. ■

Definition (`funPresentation`). The enumeration by consistent finite step constraints, with inconsistent codes assigned to the master neighbourhood, gives a computable presentation of the function space.

Theorem (`interList_cons`). Intersecting a nonempty list is intersection with its head followed by intersection of its tail.

Proof. The recursive definition intersects the head set with the intersection accumulated from the tail. ■

Theorem (`mem_interList`). A point belongs to a finite list intersection exactly when it lies in the base and in every listed set.

Proof. Induction on the list expands the head intersection, converting point membership into membership in the base and in every listed set. ■

Theorem (`rel_interList_of_selection`). A map satisfying a finite selection of constraints relates a common stronger antecedent to the intersection of their consequents.

Proof. Induction on the selected constraints first restricts each relation to the common stronger antecedent, then combines the head consequent with the tail intersection using closure under target intersection. ■

Theorem (`interList_mem_of_stepFun_nonempty`). A compatible finite selection of consequents has a neighbourhood intersection whenever the ambient step-function neighbourhood is nonempty.

Proof. Choose a map from the nonempty step neighbourhood; it satisfies every selected constraint, and the preceding finite-intersection relation makes the intersection a target neighbourhood. ■

Theorem (`stepFun_funListOf_nonempty_iff`). The finite step-function neighbourhood is nonempty exactly when every consistent selected family of antecedents has a consistent family of consequents.

Proof. Necessity follows by choosing a map satisfying the finite constraints and intersecting the selected consequents; sufficiency constructs the least map after filtering exactly the antecedents containing each source neighbourhood. ■

Theorem (`mem_interFrom`). A point belongs to the indexed iterated intersection exactly when it lies in the initial set and every enumerated factor.

Proof. Induction on the index list expands each successive intersection, giving membership in the base and in every enumerated factor. ■

Theorem (`interFrom_subset`). An iterated intersection is contained in its initial set.

Proof. The membership characterization includes membership in the initial set as its first conjunct. ■

Theorem (`interFrom_mem_of_witness`). An iterated intersection is a neighbourhood whenever it contains a neighbourhood witness and its initial set is a neighbourhood.

Proof. Induction on the index list applies neighbourhood closure under a finite intersection, using the common neighbourhood witness to certify consistency at each new factor. ■

Theorem (`interFrom_eq_of_foldl`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. Induction on the indices computes the head intersection using the presentation's intersection specification and continues from that neighbourhood on the tail. ■

Theorem (`idxchain_spec`). When the iterated intersection is a neighbourhood, the successively computed index denotes exactly that intersection.

Proof. Induction on the index list uses the presentation's computed-intersection specification at the head and continues with the resulting neighbourhood index on the tail. ■

Theorem (`bitSelect_cons`). The low mask bit decides whether the head is retained, and the halved mask selects from the tail.

Proof. The low bit decides whether to retain the head, and division by two supplies the mask for the tail. ■

Theorem (`bitSelect_sublist`). Selection by a bit mask always produces a sublist of the original list.

Proof. Induction on the source list either keeps or skips its head according to the low bit; both choices preserve the sublist relation for the recursively selected tail. ■

Theorem (`exists_bitSelect_lt`). Every sublist is selected by some bit mask smaller than the corresponding power of two.

Proof. Induction on the sublist derivation assigns an even mask when the ambient head is skipped and an odd mask when it is retained; the power-of-two bound doubles at each new position. ■

Theorem (`forall_sublist_iff_forall_bitmask`). A property holds for every sublist exactly when it holds for every sublist selected by a bounded bit mask.

Proof. Every mask selects a sublist, giving one direction; for the converse, encode an arbitrary sublist by its bounded even-and-odd mask and apply the assumed masked case. ■

Theorem (`consUpd_eval`). On an explicitly packed state, the consistency update either processes the selected entry or skips it according to the low mask bit.

Proof. Unpairing the state exposes the mask, current index and flag; the low bit then chooses between processing the entry and carrying the state forward. ■

Theorem (`consUpd_foldl_flag_zero`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. Induction on the remaining list shows that a zero success flag is absorbing: whether the next entry is selected or skipped, the recursive state still carries flag zero. ■

Theorem (`consUpd_foldl_spec`). The coded finite fold agrees with repeated application of its step function to the decoded list.

Proof. Induction on the scanned list follows the low mask bit. Skipping preserves the state; selecting intersects the current neighbourhood and updates the flag with the consistency characteristic. ■

Theorem (`consCharAt_spec`). The consistency characteristic has value one exactly when the bit-selected family has a neighbourhood intersection.

Proof. The coded-fold equation reduces the characteristic to the consistency-update fold, whose specification identifies acceptance with the selected finite intersection being a neighbourhood. ■

Theorem (`primrec_consStp`). The numerical function defining consStp is primitive recursive.

Proof. The cons step function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`primrec_consCharAt`). The numerical function defining consCharAt is primitive recursive.

Proof. The cons characteristic at function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`consFold_decidable`). Neighbourhood status of every bit-selected finite intersection is recursively decidable.

Proof. Decide consistency for each bit-selected antecedent and consequent intersection, then apply bounded universal quantification over all masks below the power-of-two bound. ■

Theorem (`interList_X_eq_interFrom`). Intersecting a list of enumerated neighbourhoods from the master set agrees with iterated intersection by their indices.

Proof. Pointwise membership on both sides is membership in the master set and in every neighbourhood named by the index list. ■

Theorem (`antecedent_cons_iff`). A finite family of antecedents has a common neighbourhood refinement exactly when its iterated intersection is a neighbourhood.

Proof. A common neighbourhood witness is contained in the iterated intersection; conversely, when that intersection is a neighbourhood, its computed presentation index supplies a common refinement of every listed antecedent. ■

Theorem (`funConsequent_eq`). The intersection of selected consequent neighbourhoods equals their iterated intersection from the master neighbourhood.

Proof. The general equality between list intersection and indexed iteration applies after mapping each selected pair to its target index. ■

Theorem (`funCons_iff`). A finite step-function neighbourhood is nonempty exactly when consistency of every selected antecedent family implies consistency of its consequent family.

Proof. The finite-consistency criterion is first expressed over every sublist, then bounded masks are used to enumerate exactly those sublists; antecedent and consequent intersections are converted to indexed iterations. ■

Theorem (`funCons_decidable`). Nonemptiness of the finite step-function neighbourhood represented by a code is recursively decidable.

Proof. Decide consistency for each bit-selected antecedent and consequent intersection, then apply bounded universal quantification over all masks below the power-of-two bound. ■

Theorem (`selectFn_one_iff_imp`). For a zero-one antecedent, selection with default one returns one exactly when value one of the antecedent forces value one of the consequent.

Proof. Since the control is at most one, it is either zero or one; the two selector equations turn these cases into the truth table for implication. ■

Theorem (`funConsChar_spec`). The function-space consistency characteristic has value one exactly when the represented finite step-function neighbourhood is nonempty.

Proof. The coded fold specification turns each selected mask into a finite neighbourhood intersection, and bounded universal quantification ranges over exactly all sublists. ■

Theorem (`primrec_funImpChar`). The numerical function defining funImpChar is primitive recursive.

Proof. The fun imp characteristic function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`primrec_funConsChar`). The numerical function defining funConsChar is primitive recursive.

Proof. The fun cons characteristic function is built from primitive-recursive projections, constants, pairing and composition. ■

Theorem (`funSpace_isEffectivelyGiven`). The funSpace neighbourhood system is effectively given.

Proof. Choose computable presentations for source and target, build the finite-step enumeration with its primitive-recursive consistency characteristic, and use it as the required function-space presentation. ■

Theorem (`Xenum_singleton`). The code for a singleton source-target constraint denotes the corresponding one-step function-space neighbourhood.

Proof. The successor list code decodes to the single paired index; consistency of a valid one-step constraint selects its step neighbourhood rather than the master case. ■

Theorem (`consChain_iff`). The computed intersection index lies below every index in the chain exactly when the corresponding iterated intersection is a neighbourhood.

Proof. If the computed neighbourhood lies below every factor, it witnesses that their intersection is a

neighbourhood; conversely, the intersection specification identifies the computed neighbourhood with that intersection. ■

Theorem (`evalMap_rel_prodNbhd_iff`). Evaluation relates a product neighbourhood to a target neighbourhood exactly when every function in the function component sends the argument neighbourhood into that target neighbourhood.

Proof. The definition of evaluation reduces the product coordinates to the function neighbourhood and argument neighbourhood; its relation is precisely pointwise membership in the target step. ■

Theorem (`evalMap_isComputable`). Evaluation from the product of a presented function space and its source is computable.

Proof. Evaluation on a product neighbourhood is equivalent to inclusion of its function component in a one-step neighbourhood; the function-space presentation makes this inclusion decidable. ■

Theorem (`funListOf_append`). Interpreting a concatenation of index lists gives the concatenation of their interpreted neighbourhood-pair lists.

Proof. Interpretation is list mapping by paired indices, and mapping distributes over concatenation. ■

Theorem (`interList_subset_base`). The iterated intersection is contained in its initial base set.

Proof. Induction on the list expands the head intersection, converting point membership into membership in the base and in every listed set. ■

Theorem (`mem_Xenum_iff`). A function-space element contains an enumerated neighbourhood exactly when it satisfies every decoded step constraint whenever the code is consistent.

Proof. A successful code reduces membership to all decoded step constraints; a failed code denotes the master neighbourhood, which every function-space element contains. ■

Theorem (`Xenum_isComputableElement_iff`). Computability of the function-space element is equivalent to computability of its associated approximable map.

Proof. Singleton constraint codes recover the relation of the associated approximable map in one direction; in the other, finite universal closure combines that recursively enumerable relation over every decoded list. ■

Theorem (`isComputableElement_funPresentation_iff`). Computability of the function-space element is equivalent to computability of its associated approximable map.

Proof. This is the preceding equivalence after unpacking the definitions of computable element and computable map. ■

Theorem (`mem_Xenum_iff_map`). An approximable map belongs to an enumerated function neighbourhood exactly when every decoded relation holds whenever the code is consistent.

Proof. A successful code is membership in the finite step neighbourhood, hence satisfaction of every decoded relation; a failed code is the whole space. ■

Theorem (`curry_rel_Xenum_iff`). A curried map relates an outer antecedent to an enumerated function neighbourhood exactly when the original map satisfies every decoded product constraint.

Proof. The section of the original map at the outer antecedent satisfies exactly the decoded inner step constraints; recursive enumerability follows by finite universal quantification over the decoded list. ■

Theorem (`curry_isComputable`). Currying a computable map on the product presentation yields a computable map into the presented function space.

Proof. Rewrite the curried relation as an implication from consistency to all decoded product constraints; recursive enumerability follows from finite universal closure and disjunction with failure of the primitive-recursive consistency test. ■

Definition (`curryStepCode`). This code represents the singleton step constraint obtained by adjoining a fixed outer antecedent to an inner antecedent-consequent pair.

Theorem (`curryIso_apply`). The currying isomorphism sends an element to the filter generated by the curried associated approximable map.

Proof. The equality is the defining action of the currying isomorphism on an element represented by its associated approximable map. ■

Theorem (`primrec_curryStepCode`). The numerical function defining curryStepCode is primitive recursive.

Proof. The curry step code function is built from primitive-recursive projections, constants, pairing and composition. ■

4.8.13 Theorem 7.5 — function space effective

THEOREM 7.5. If $\mathcal{D}_0$ and $\mathcal{D}_1$ are effectively given, then so is $(\mathcal{D}_0 \to \mathcal{D}_1)$. The combinators eval and curry are computable, provided all the domains involved are effectively given. The computable elements $f \in |\mathcal{D}_0 \to \mathcal{D}_1|$ are exactly the computable maps $f : \mathcal{D}_0 \to \mathcal{D}_1$.

Proof: The proofs of 3.9, 3.11, and 3.12 were set up with this theorem in mind. If

$$\mathcal{D}_0 = \{X_n \mid n \in \mathbf{N}\} \quad \text{and} \quad \mathcal{D}_1 = \{Y_m \mid m \in \mathbf{N}\}$$

are two effectively given neighbourhood systems, then the neighbourhoods of $(\mathcal{D}_0 \to \mathcal{D}_1)$, by Definition 3.8, are non-empty intersections like

$$\bigcap_{i<q} [X_{n_i}, Y_{m_i}],$$

where $\langle n_0, n_1, \ldots, n_{q-1}\rangle$ and $\langle m_0, m_1, \ldots, m_{q-1}\rangle$ are two finite sequences of integers determining the choice of the function-space neighbourhood. In 3.9(i) the test for nonemptiness is given. Assuming the decidability of relations in $\mathcal{D}_0$ and $\mathcal{D}_1$, one remarks that the consistency of *finite sequences* of neighbourhoods is also decidable. (Hint: Test the first *two*, then form their intersection. Next test the third given neighbourhood against this one set; if consistent, form the intersection, and carry on.) By 3.9(i) at most $2 \cdot 2^q$ such sequential checks must be carried out to determine whether the function-space neighbourhood is non empty.

It may not be fun, but the checks can be carried out in finite time. Owing to this decidability, we can therefore enumerate in a systematic way *all* the pairs of finite sequences $\langle n_0, \ldots\rangle$ and $\langle m_0, \ldots\rangle$ that determine neighbourhoods: that is the way that $(\mathcal{D}_0 \to \mathcal{D}_1)$ obtains its enumeration.

Concerning the decidability of the required relations on $(\mathcal{D}_0 \to \mathcal{D}_1)$, we remark first off that consistency is more of the same: to test two finite intersections against each other, just form one big intersection and test it for non-emptiness as before. Secondly, the testing for intersection comes down in the end to testing one typical intersection of $[X, Y]$-neighbourhoods for equality with another. But equality amounts to two inclusions; inclusion in an intersection amounts to inclusion in each term. Therefore, what we need to do is to check a finite number of statements of the form:

$$\bigcap_{i<q}[X_{n_i}, Y_{m_i}] \subseteq [X_k, Y_\ell].$$

As we pointed out after the proof of 3.9, this inclusion is equivalent to

$$\bigcap\{Y_{m_i} \mid X_k \subseteq X_{n_i}\} \subseteq Y_\ell.$$

By decidability in $\mathcal{D}_0$, we can effectively find the n_i that are needed. Then in $\mathcal{D}_1$, we form the intersection of the corresponding Y_{m_i}. Finally, we check the inclusion. Again, one check in $(\mathcal{D}_0 \to \mathcal{D}_1)$ requires a whole sequence of checks in $\mathcal{D}_0$ and in $\mathcal{D}_1$, but the process is finite. So we have argued that $(\mathcal{D}_0 \to \mathcal{D}_1)$ is effectively given.

In showing that the combinators are computable, we refer first to the proof of 3.11. The typical pair of neighbourhoods possibly belonging to eval is

$$\bigcap_{i<q}[X_{n_i}, Y_{m_i}],\ X_k \text{ eval } Y_\ell.$$

As we needed not to be so specific, we expressed the holding of this relationship in terms of *all* the functions in the function-

space neighbourhood. But we know that the neighbourhood, by 3.9(ii), has a minimal element; it is then sufficient to test for the holding of $X_k f_0 Y_\ell$ at this minimal function f_0. But this test, we have already seen, is decidable. So the pairs in eval actually form a recursive set, not just a recursively enumerable set; thus, eval is a computable function.

The case of curry involves three domains and is a bit more messy. But again, if the required neighbourhoods are written out in full, it will be seen that curry, too, is computable. We leave this minor struggle to the exercises.

The final statement is an easy consequence of the fundamental connection between approximable $f : \mathcal{D}_0 \to \mathcal{D}_1$ as relations and as elements. Recall, as in the proof of 3.10, that we have

$$f \in [X, Y] \text{ iff } X f Y,$$

for all $X \in \mathcal{D}_0$ and $Y \in \mathcal{D}_1$. Therefore,

$$f \in \bigcap_{i<q}[X_{n_i}, Y_{m_i}] \text{ iff } \forall i < q.\ X_{n_i} f Y_{m_i}.$$

It follows that if f is recursively enumerable as a set of pairs, then, by forming all the non-empty intersections (as shown), we get an enumeration of all the neighbourhoods to which f belongs; and this is

the same as the filter corresponding to f as an element of the function space. The converse direction is clear. □

We have nearly all our favourite combinators computable, but perhaps the most important one - since it is the key to recursive definitions - is the fixed-point combinator. It is not left out.

The development is with the function-space presentation peer.

Theorem (`theorem_75`). If two neighbourhood systems are effectively given, then so is their function space. Evaluation and currying are computable, and the computable elements of the function space are exactly the computable maps.

Proof. By the function-space presentation. ■

4.8.15 Theorem 7.6 — fix is computable

THEOREM 7.6. For any effectively given domain $\mathcal{D}$, the combinator fix : $(\mathcal{D} \to \mathcal{D}) \to \mathcal{D}$ is computable.

Proof : Referring back to the proof of Theorem 4.2 and thinking of

$$\mathcal{D} = \{X_n \mid n \in \mathbb{N}\}$$

as effectively given, fix as a relation comes down to

$$\bigcap_{i<q} [X_{n_i}, X_{m_i}] \text{ fix } X_\ell \text{ iff for some finite sequence}$$

$$\Delta = X_{k_0}, \ldots, X_{k_p} = X_\ell,$$

we have, for each $j < p$,

$$\bigcap \{X_{m_i} \mid X_{k_j} \subseteq X_{n_i}\} \subseteq X_{k_{j+1}}.$$

Inside the "for some finite sequence" all the checks are decidable by assumption on D. But the existential quantification of a decidable predicate always gives a recursively enumerable predicate. (And, as there is no implied bound on the size of the finite sequence we are looking for, this really *is* an enumerable set and not generally a recursive set.) □

The major consequence of what we have done up to this point concerns typed λ-calculus. Any expression involving only *effectively given types* and, perhaps, some *basic computable constants* using only the $\lambda, !$-notation defines a computable function of its free variables. And such functions applied to computable arguments give computable values. And such functions have computable least fixed points. Etc., etc. In a definite sense then we have in the "metalanguage", as people say, a quite precise and fully *mathematical programming language* for defining computable operators. It is not a machine implemented language, but it is a mathematically well-defined and easy-to-use language. And when we combine the usual type-definition facility together with *domain equations*, we have an especially powerful language.

The development is with the computable fixpoint peer.

Theorem (`theorem_76`). On an effectively given domain, the fixpoint combinator is computable.

Proof. By the computable fixpoint map. ■

4.8.16 Effectively given lists

The list domain over an effectively given neighbourhood system is effectively given.

Definition (`Proposition77.consB`). The consistency component of a packed triple is the first coordinate of its second coordinate.

Definition (`Proposition77.eqB`). The equality component of a packed triple is its first coordinate.

Definition (`Proposition77.intI`). The intersection-index component of a packed triple is the second coordinate of its second coordinate.

Theorem (`Proposition77.le_pair_left`). The left coordinate of a paired natural number does not exceed the pair code.

Proof. This follows directly from the quadratic pairing formula. ■

Definition (`Proposition77.listGetStp`). The list lookup step decrements a counter and, exactly when the counter is one, replaces the stored value by the current list entry.

Definition (`Proposition77.listGet`). The coded-list lookup function folds the lookup step through a coded list and returns the stored value, using zero as the default.

Theorem (`Proposition77.listGetStp_pair`). On a state with counter c, value v, and current entry x, the lookup step returns counter $c - 1$ and selects x precisely when $c = 1$.

Proof. Unpack the state and apply the definition of the step. ■

Theorem (`Proposition77.listGet_foldl_zero`). Folding the lookup step from counter zero leaves the stored value unchanged.

Proof. Induct on the list; a zero counter never selects a list entry. ■

Theorem (`Proposition77.listGet_foldl`). Folding from counter $c + 1$ returns the list entry at position c, or the supplied default if that position is absent.

Proof. Induct on the list, separating the zero and successor cases of c. ■

Theorem (`Proposition77.listGet_encodeList`). Looking up index i in an encoded list returns its i-th entry, with default zero.

Proof. Coded folding agrees with list folding, to which the preceding lookup identity applies. ■

Theorem (`Proposition77.max_sq_le_pair`). The square of the larger of two natural numbers is at most their pair code.

Proof. Expand the pairing formula and separate the two possible coordinate orders. ■

Theorem (`Proposition77.memS_sub_embPair`). A list neighbourhood contained in an embedded pair is itself an embedded pair of list neighbourhoods.

Proof. The master and zero-embedded forms contain paths incompatible with a pair; only the paired constructor remains. ■

Theorem (`Proposition77.memS_sub_embZero`). A list neighbourhood contained in an embedded zero neighbourhood is itself the zero embedding of an original neighbourhood.

Proof. Nonemptiness rules out the master and paired forms by their incompatible path shapes. ■

Theorem (`Proposition77.nat_shape`). Every natural number is either zero, positive odd, or positive even.

Proof. A positive number is classified by its remainder modulo two. ■

Definition (`Proposition77.packT`). Three natural numbers are packed as a pair whose second coordinate is itself a pair.

Theorem (`Proposition77.eqB_packT`). The equality projection of a packed triple returns its first entry.

Proof. Unpair twice. ■

Theorem (`Proposition77.consB_packT`). The consistency projection of a packed triple returns its second entry.

Proof. Unpair twice. ■

Theorem (`Proposition77.intI_packT`). The intersection-index projection of a packed triple returns its third entry.

Proof. Unpair twice. ■

Definition (`Proposition77.dsharpStep`). The list-domain decision step classifies two neighbourhood indices as master, zero-embedded, or paired, and packs equality, consistency, and intersection information using supplied base-system procedures and earlier table entries.

Theorem (`Proposition77.dsharpStep_i0`). If the first index is zero, the decision step reports consistency, returns the second index as intersection, and reports equality exactly when the second index is zero.

Proof. The first master-index branch is selected. ■

Theorem (`Proposition77.dsharpStep_j0`). If the second index is zero and the first is nonzero, the decision step reports consistency, returns the first index as intersection, and reports inequality.

Proof. The second master-index branch is selected. ■

Theorem (`Proposition77.dsharpStep_ll`). For two odd indices, the decision step applies the supplied base equality, consistency, and intersection procedures to their decoded indices and repacks the

intersection as odd.

Proof. Both parity tests select the zero-embedded branch. ■

Theorem (`Proposition77.dsharpStep_ln`). For an odd first index and a positive even second index, the decision step returns three zero components.

Proof. The two neighbourhoods have incompatible zero and pair shapes. ■

Theorem (`Proposition77.dsharpStep_nl`). For a positive even first index and an odd second index, the decision step returns three zero components.

Proof. The two neighbourhoods have incompatible pair and zero shapes. ■

Theorem (`Proposition77.dsharpStep_nn`). For two positive even indices, the decision step combines the two recursively tabulated component results: equality and consistency are products, and the intersection index pairs the two component intersection indices.

Proof. Both parity tests select the paired branch and the decoded child pairs address earlier table entries. ■

Theorem (`Proposition77.pair_lt_succ_sq`). A pair code is smaller than the square of one plus its largest coordinate.

Proof. Expand the pairing formula in each coordinate order. ■

Theorem (`Proposition77.pair_lt_pair_of_lt`). Strict coordinatewise inequalities imply a strict inequality between pair codes.

Proof. Bound the smaller code by the next square and the larger code below by the square of its largest coordinate. ■

Theorem (`Proposition77.primrec_listGet`). Coded-list lookup is primitive recursive.

Proof. Its step, initial state, coded fold, and final projection are all primitive recursive. ■

Theorem (`Proposition77.primrec_listGet2`). Substituting primitive-recursive code and index functions into coded-list lookup yields a primitive-recursive function.

Proof. Pair the two arguments and compose with primitive-recursive lookup. ■

Theorem (`Proposition77.primrec_dsharpStep`). If the supplied base consistency, equality, and intersection functions are primitive recursive, then the list-domain decision step is primitive recursive.

Proof. Every branch condition, table address, projection, product, pairing, and packed result is primitive recursive, and finite numerical selection preserves this property. ■

Definition (`Proposition77.rtbl`). The recursion table at stage zero is empty; at stage $w + 1$ it prepends the result of applying the step at w to the previous table.

Definition (`Proposition77.gOf`). The value generated at stage w is the step applied to w together with the table of earlier values.

Definition (`Proposition77.gList`). The generated list at stage $w + 1$ has the stage-w value at its head followed by the list from stage w.

Theorem (`Proposition77.gOf_def`). The generated value is the step evaluated at its stage and recursion table.

Proof. This is the definition. ■

Theorem (`Proposition77.getD_gList`). For $p < w$, position p in the generated list at stage w contains the value generated at stage $w - 1 - p$.

Proof. Induct on w, separating the head position from successor positions. ■

Theorem (`Proposition77.rtbl_eq_encode`). The recursion table at stage w is the code of the generated list at that stage.

Proof. Induct on w; both constructions prepend the newly generated value. ■

Theorem (`Proposition77.listGet_rtbl`). If $v < w$, lookup at reverse position $w - 1 - v$ in the stage-w table returns the value generated at stage v.

Proof. Replace the table by its encoded generated list and use the reverse-position formula. ■

Theorem (`Proposition77.rtbl_eq_rec`). The recursion table agrees with ordinary natural-number recursion that prepends each new step result.

Proof. Induct on the stage. ■

Theorem (`Proposition77.primrec_rtbl`). A primitive-recursive step has a primitive-recursive recursion table.

Proof. The table is obtained by primitive recursion with primitive-recursive pairing and successor operations. ■

Theorem (`Proposition77.primrec_gOf`). A primitive-recursive step has a primitive-recursive generated-value function.

Proof. Pair the stage with its primitive-recursive table and apply the step. ■

Theorem (`Proposition77.unpair_fst_le`). The first coordinate decoded from a natural number does not exceed that number.

Proof. The number is the pair of its decoded coordinates, and the left coordinate is bounded by its pair code. ■

Definition (`Proposition77.Vsharp`). The list neighbourhood at index zero is the master neighbourhood; positive odd indices encode zero embeddings of base neighbourhoods, and positive even indices encode pairs of recursively indexed list neighbourhoods.

Theorem (`Proposition77.Vsharp_succ`). The successor case of the enumeration is the odd zero-embedding branch or the even paired branch according to parity.

Proof. This is the recursive defining equation. ■

Theorem (`Proposition77.Vsharp_even`). The neighbourhood indexed by $2n + 2$ is the embedded pair of the neighbourhoods at the two coordinates decoded from n.

Proof. The index is positive even, and its predecessor decodes back to n. ■

Theorem (`Proposition77.Vsharp_even_inter_even`). The intersection of two even-indexed neighbourhoods is the embedded pair of the intersections of their corresponding components.

Proof. Expand both even indices and distribute intersection through embedded pairing. ■

Theorem (`Proposition77.Vsharp_odd`). The neighbourhood indexed by $2n + 1$ is the zero embedding of the base neighbourhood indexed by n.

Proof. The index is positive odd. ■

Theorem (`Proposition77.Vsharp_odd_inter_even`). An odd-indexed neighbourhood and an even-indexed neighbourhood have empty intersection.

Proof. Zero embeddings and pair embeddings have disjoint path shapes. ■

Theorem (`Proposition77.Vsharp_even_inter_odd`). An even-indexed neighbourhood and an odd-indexed neighbourhood have empty intersection.

Proof. Commute the intersection and use the odd-even case. ■

Theorem (`Proposition77.Vsharp_odd_inter_odd`). The intersection of two odd-indexed neighbourhoods is the zero embedding of the intersection of their base neighbourhoods.

Proof. Expand both odd indices and distribute intersection through zero embedding. ■

Theorem (`Proposition77.Vsharp_zero`). Index zero enumerates the master list neighbourhood.

Proof. This is the base case of the enumeration. ■

Theorem (`Proposition77.Vsharp_eq_Gamma_iff`). When all base neighbourhoods are nonempty, an enumerated list neighbourhood is master exactly when its index is zero.

Proof. Odd and positive even indices have zero or pair shape, each distinct from the master shape. ■

Theorem (`Proposition77.Vsharp_mem`). Every enumerated $V^\sharp$ family is a list neighbourhood.

Proof. Strong induction follows the zero, odd zero-embedding, and even paired clauses of the enumeration. ■

Theorem (`Proposition77.Vsharp_inter_zero`). Intersecting any enumerated neighbourhood on the right with index zero leaves it unchanged.

Proof. Index zero is master and every list neighbourhood lies within the master neighbourhood. ■

Theorem (`Proposition77.Vsharp_nonempty`). If every base neighbourhood is nonempty, every enumerated list neighbourhood is nonempty.

Proof. Every list neighbourhood built from a nonempty base system is nonempty. ■

Theorem (`Proposition77.Vsharp_surj`). Every list neighbourhood occurs in the $V^\sharp$ enumeration.

Proof. Induct over its master, zero-embedded, and paired construction, using surjectivity of the base presentation and pairing of the recursive indices. ■

Theorem (`Proposition77.Vsharp_zero_inter`). Intersecting index zero on the left with any enumerated neighbourhood leaves it unchanged.

Proof. Index zero is master. ■

Theorem (`Proposition77.exists_sub_embPair_iff`). An enumerated list neighbourhood lies inside an embedded pair of A, B exactly when some enumerated neighbourhood lies inside A and some enumerated neighbourhood lies inside B.

Proof. Any list neighbourhood inside a pair has paired components, and surjectivity enumerates them; conversely pair two witnessing neighbourhoods. ■

Theorem (`Proposition77.exists_sub_embZero_iff`). An enumerated list neighbourhood lies inside the zero embedding of Y exactly when some enumerated base neighbourhood lies inside Y.

Proof. Any list neighbourhood inside a zero embedding has zero shape, and base-presentation surjectivity identifies its generator; the converse uses the corresponding odd index. ■

Theorem (`Proposition77.dsharp_decider_spec`). The generated packed decision value correctly reports consistency, supplies an intersection index when consistent, and reports equality for every pair of enumerated list neighbourhoods.

Proof. Strong induction on the pair code follows the master, odd, and even shape cases; paired inputs reduce to two strictly smaller component pairs, while mixed shapes are disjoint. ■

Theorem (`Proposition77.dsharp_intI_correct`). Whenever two enumerated list neighbourhoods are consistent, the generated intersection component indexes their intersection.

Proof. The same strong induction on shape uses the supplied base intersection specification and recursively combines paired components. ■

Theorem (`Proposition77.dsharp_interEq_iff`). Equality of an intersection $V_n^\sharp \cap V_m^\sharp$ with $V_k^\sharp$ is equivalent to the product of the generated consistency bit and the equality bit comparing the generated intersection index with k being one.

Proof. Consistency supplies the correct intersection index, after which the generated equality decision tests it against k. ■

Definition (`Proposition77.dsharpPresentation`). The effective presentation of the list system uses $V^\sharp$, the generated decision procedure for equality and consistency, the generated intersection index, and zero as master index.

Proof. The enumeration is surjective, all decision functions are primitive recursive, the intersection component is correct, and index zero denotes the master neighbourhood. ■

Theorem (`Proposition77.dsharp_isEffectivelyGiven`). If the base system has a computable presentation and all its neighbourhoods are nonempty, then its list system is effectively given.

Proof. Use the constructed list-system computable presentation. ■

Theorem (`Proposition77.dsharpPresentation_X`). The neighbourhood enumerated at n by the list-system presentation is $V^{\sharp}_{n}$.

Proof. This is the presentation's enumeration. ■

Definition (`Proposition77.inSharpMap`). The list insertion relation sends a base neighbourhood X to list neighbourhoods containing its zero embedding.

Proof. The relation contains the master case, is closed under target intersections, and is monotone. ■

Theorem (`Proposition77.inSharpMap_rel`). Insertion relates X to W exactly when both are valid neighbourhoods and the zero embedding of X is contained in W.

Proof. This is the defining relation. ■

Definition (`Proposition77.proj0Map`). The first projection relation sends the master target universally and sends a paired source to targets containing its left component.

Proof. Component uniqueness gives intersection closure, and refinement of a paired source refines its left component. ■

Theorem (`Proposition77.proj0Map_rel`). The first projection relates W to Z exactly when both are list neighbourhoods and either Z is master or W is a pair whose left component lies inside Z.

Proof. This is the defining relation. ■

Theorem (`Proposition77.inSharpMap_toElementMap`). On elements, the insertion approximable map is the canonical zero-branch insertion into the list domain.

Proof. A list neighbourhood containing a zero-embedded source neighbourhood is either master or a zero embedding of a neighbourhood of the source element. ■

Theorem (`Proposition77.inSharp_isComputable`). The insertion approximable map is computable.

Proof. At presentation indices its relation is decidable inclusion from the corresponding odd-indexed zero embedding. ■

Theorem (`Proposition77.proj0_rel_Vsharp_iff`). The first projection relates indices m, k exactly when $k = 0$, or m is nonzero even and the decoded left component of m is contained in k.

Proof. Separate the master, odd zero-embedded, and even paired forms of the source. ■

Theorem (`Proposition77.proj0_isComputable`). The first projection approximable map is computable.

Proof. Its indexed criterion combines decidable zero, parity, and nonzero tests with decidable inclusion of the decoded left component. ■

Theorem (`Proposition77.proj0_toElementMap_pairSharp`). Applying the first projection to a paired list-domain element returns its first component.

Proof. Target membership is equivalent to containing a left-component neighbourhood of the pair. ■

Theorem (`Proposition77.gList_length`). The generated list at stage w has length w.

Proof. Induct on w; each successor stage prepends one value. ■

4.8.17 List combinators

Pairing and the projections on the list domain are computable.

Definition (`Proposition77.proj1Map`). The second projection relation sends the master neighbourhood to every master target and sends a paired neighbourhood to targets containing its right component.

Proof. The relation contains the master pair, is closed under target intersections, and is monotone under refinement of source and enlargement of target. ■

Theorem (`Proposition77.proj1Map_rel`). The second projection relates W to Z exactly when both are list neighbourhoods and either Z is master or W is a pair whose right component is contained in Z.

Proof. This is the defining relation. ■

Definition (`Proposition77.pairSharpMap`). The pairing relation sends a product neighbourhood generated by A, B to every list neighbourhood containing the embedded pair of A and B.

Proof. Pairing master neighbourhoods gives the master case; intersections and monotonicity follow componentwise. ■

Theorem (`Proposition77.pairSharpMap_rel`). A product neighbourhood V is related to W exactly when V is generated by list neighbourhoods A, B and the embedded pair of A, B is contained in W.

Proof. This is the defining relation. ■

Theorem (`Proposition77.pairSharpMap_toElementMap`). On elements, the pairing approximable map is the list-domain pairing operation.

Proof. A target neighbourhood is obtained from component neighbourhoods exactly when it contains their embedded pair. ■

Theorem (`Proposition77.pairSharp_rel_Vsharp_iff`). At presentation indices t, k, the pairing relation holds exactly when the paired list neighbourhood indexed by $2t + 2$ is contained in the neighbourhood indexed by k.

Proof. Decode t into its two product indices and use the even-index formula for list neighbourhoods. ■

Theorem (`Proposition77.pairSharp_isComputable`). The pairing approximable map on the list domain is computable.

Proof. Its indexed relation reduces to decidable inclusion after the primitive-recursive transformation $(t, k) \mapsto (2t + 2, k)$. ■

Theorem (`Proposition77.proj1_rel_Vsharp_iff`). The second projection relates the neighbourhood indexed by m to that indexed by k exactly when k is the master index, or m is nonzero and even and its decoded right component is contained in k.

Proof. Separate the master, zero-embedded, and paired forms of the source; only a paired source has a right component. ■

Theorem (`Proposition77.proj1_isComputable`). The second projection approximable map is computable.

Proof. The criterion uses decidable tests for zero, parity, and nonzeroness, together with decidable inclusion of the decoded right component. ■

Theorem (`Proposition77.proj1_toElementMap_pairSharp`). Applying the second projection to a paired list-domain element returns its second component.

Proof. A target neighbourhood belongs to the image exactly when it contains a right-component neighbourhood of the pair. ■

4.8.18 Proposition 7.7 — lists effectively given

PROPOSITION 7.7. For any effectively given domain D, the domain $D^{\S}$ is also effectively given, and all the combinators of Example 6.1 prove to be computable.

Proof: This proof is essentially an exercise, but it is useful to have an easy-to-grasp example. Indeed, to make things easy to reason about, we can assume that D is a system over $\Delta = \mathbf{N}$, and that in the presentation where

$$D = \{X_n \mid n \in \mathbf{N}\},$$

the relation $k \in X_n$ is *recursive* in k and n. (It is worth thinking why this is so.) Of course, a lot of other things are recursive also.

Now what kind of a system is $D^{\S}$? The construction of 6.1 made it a system over a certain set of strings Γ. For the sake of checking various assertions about computability, we are transposing everything back to $\mathbf{N}$. (These are all denumerable sets in any case.) The set Γ is divided into three equally big parts, and we can do the same for $\mathbf{N}$. Let us write for any $m, k \in \mathbf{N}$ and subset $X \subseteq \mathbf{N}$:

$$mX + k = \{m \cdot n + k \mid n \in X\}.$$

Then by splitting the integers modulo 3 we have:

$$\mathbf{N} = 3\mathbf{N} \cup (3\mathbf{N} + 1) \cup (3\mathbf{N} + 2),$$

and this equation is quite analogous to that for Γ. We then propose this definition for $D^{\S}$:

$$D^{\S} = \{\mathbf{N}\} \cup \{3X \mid X \in D\} \cup \{(3X + 1) \cup (3Y + 2) \mid X, Y \in D^{\S}\},$$

but this does not make the enumeration of $D^{\S}$ all that obvious. This is one way to do it:

$$V_0 = \mathbf{N}\ ;\ V_{2n+1} = 3X_n\ ;\ V_{2n+2} = (3V_{p(n)} + 1) \cup (3V_{q(n)} + 2).$$

Here p and q are the inverse of the pairing functions mentioned in 7.4. They must be chosen so that $p(n) < n$ and $q(n) < n$ for all $n \in \mathbf{N}$. Thus, in calculating V_k where $k = 2n + 2$ we will be using $V_{p(n)}$ and $V_{q(n)}$ where both subscripts are strictly less than k. This observation is required so that $m \in V_k$ is going to be a recursive relation. What we claim is that

$$D^{\S} = \{V_k \mid k \in \mathbf{N}\}.$$

It should be clear that everything on the right belongs to $D^{\S}$. What needs an inductive argument is that everything in $D^{\S}$ is eventually of the form V_k. But this should be fairly obvious owing to the properties of $r : \mathbf{N} \times \mathbf{N} \leftrightarrow \mathbf{N}$.

The reader also has to check that 7.1(i)–(ii) hold for the V_k. The idea is that any such check is either (1) trivial, or (2) something already assumed about D and the X_n, or (3) can be thrown back to some sets V_m with strictly smaller subscripts. Therefore, the checks will give an answer in finite time according to an effective reduction.

Next for the combinators, we have to translate neighbourhood relations into relations among integer indices. A selection of examples must suffice,

$$X_n\ (\lambda x.\, x^{\S})\ V_k \text{ iff } V_{2n+1} \subseteq V_k$$

$$V_m\ \mathrm{proj}_0\ V_k \text{ iff } k = 0 \text{ or } \exists n \in \mathbf{N}.\, m = 2n+2 \text{ and } V_{p(n)} \subseteq V_k.$$

The reader should write out other cases. □

The development is with the effectively given lists and list combinators peers.

Theorem (`proposition_77`). For an effectively given neighbourhood system, the domain of lists over it is effectively given.

Proof. By the effective presentation of the list domain. ■

4.8.19 Powerset neighbourhoods

The powerset of the naturals is a neighbourhood system whose neighbourhoods are the cofinite complements of finite sets of bits.

Definition (`nbhd`). The neighbourhood coded by a natural number n consists of the bit positions at which n has value false.

Theorem (`mem_nbhd`). A natural number k belongs to the neighbourhood coded by n exactly when the k-th bit of n is false.

Proof. This is the defining membership condition. ■

Theorem (`nbhd_injective`). Distinct natural-number codes determine distinct neighbourhoods.

Proof. Equality of the neighbourhoods gives equality of the truth value of every bit, and natural numbers are determined by their bits. ■

Theorem (`nbhd_inter`). The intersection of the neighbourhoods coded by n and m is the neighbourhood coded by their bitwise disjunction.

Proof. A bit is false in the disjunction exactly when it is false in both operands. ■

Theorem (`nbhd_zero`). The neighbourhood coded by zero is the whole set of natural numbers.

Proof. Every bit of zero is false. ■

Definition (`PN`). The powerset neighbourhood system on the natural numbers has precisely the coded neighbourhoods, with the whole set as master neighbourhood.

Proof. Zero codes the master neighbourhood, and bitwise disjunction codes intersections. ■

Definition (`PNpres`). The canonical computable presentation enumerates the neighbourhood coded by n at index n, uses bitwise disjunction for intersection, and uses zero for the master index.

Proof. Injectivity of the coding decides equality, bitwise disjunction computes intersections, and every pair of neighbourhoods is consistent. ■

Theorem (`PN_consistent`). Any two coded neighbourhoods have a coded neighbourhood contained in their intersection.

Proof. Their bitwise disjunction codes the intersection itself. ■

Theorem (`PN_isEffectivelyGiven`). The powerset neighbourhood system is effectively given.

Proof. The canonical computable presentation supplies the required effective enumeration and operations. ■

4.8.20 Example 7.8 — powerset effectively given

EXAMPLE 7.8. We have often made reference to the powerset $P\mathbf{N}$ as a domain and we should check here that it is effectively given. One easy way to see this is to note

$$P\mathbf{N} \cong |T^\infty|.$$

The (slight) trouble with $P\mathbf{N}$ is that we usually think of it in terms of *elements* rather than *neighbourhoods*. Going back to Exercise 1.16, we can argue that the neighbourhoods of $P\mathbf{N}$ are ordered not like the finite sets of integers but in the partial ordering *converse* to that. But this is of no trouble, since all will be decidable. What we need first is an enumeration of all finite sets of integers. We can do this by:

$$E_n = \{k \mid \exists i, j.\, i < 2^k \text{ and } n = i + 2^k + j \cdot 2^{k+1}\}.$$

The idea is that $k \in E_n$ means that the exponent k does occur in the binary expansion of n as a sum of powers of 2. All finite subsets of $\mathbf{N}$ are of the form E_n. We then find that as a neighbourhood system

$$(P\mathbf{N}) = \{\mathbf{N} \setminus E_n \mid n \in \mathbf{N}\}.$$

As the relationship $E_n \cup E_m = E_k$ is recursive, there is no trouble in proving that this is a computable presentation. In this system, of course, any two neighbourhoods are consistent. Various combinators on $P\mathbf{N}$ are suggested in Exercise 7.23. □

We end this chapter with an example of another kind of domain construct. This construct is known as the *Smyth Power Domain*. It is defined for any neighbourhood system $\mathcal{D}$ and results in a new system we shall call here $\mathbb{P}\mathcal{D}$. The elements of $\mathbb{P}\mathcal{D}$ behave rather like *sets of elements* of $\mathcal{D}$, but since our elements can be either partial or total, there are certain dangers to pushing the analogy too far. For some purposes a rival construct called the *Plotkin Power Domain* is better, but it leads outside the category of neighbourhood systems as defined in these lectures. Do not confuse $P\mathbf{N}$ with $\mathbb{P}\mathcal{D}$.

The development is with the powerset neighbourhoods peer.

Theorem (`example_78`). The powerset of the natural numbers is effectively given.

Proof. By the powerset presentation. ■

4.8.21 Power domain

The powerdomain of a neighbourhood system consists of the neighbourhoods that are finite unions of upper sets.

Definition (`NeighborhoodSystem.PDmem`). A powerdomain neighbourhood is a finite union of upper sets generated by neighbourhoods of the original system.

Definition (`NeighborhoodSystem.dagger`). The dagger system is the upper-set power system associated with the original neighbourhood system.

Theorem (`NeighborhoodSystem.PDmem_union`). The union of two powerdomain neighbourhoods is a powerdomain neighbourhood.

Proof. Concatenate finite lists of generators; the resulting union is the union of the two original finite unions. ■

Theorem (`NeighborhoodSystem.dagger_isomorphic`). Every neighbourhood system is domain-isomorphic to its dagger system.

Proof. This is the canonical isomorphism between a system and its upper-set power presentation. ■

Theorem (`NeighborhoodSystem.dagger_upSet_inter`). If X, Y, Z are neighbourhoods and $Z \subseteq X \cap Y$, then the intersection of the upper sets generated by X and Y is a dagger neighbourhood.

Proof. The intersection is the upper set generated by $X \cap Y$, which is a neighbourhood because it contains the neighbourhood Z. ■

Theorem (`NeighborhoodSystem.mem_PDunion`). A set belongs to the finite union generated by a list exactly when it belongs to the upper set generated by some member of the list.

Proof. This is the elementwise meaning of a union indexed first by the list and then by membership in it. ■

Theorem (`NeighborhoodSystem.PDmem_empty`). The empty family is a powerdomain neighbourhood.

Proof. It is generated by the empty list. ■

Theorem (`NeighborhoodSystem.PDmem_iff_fin`). A family is a powerdomain neighbourhood exactly when it is a union of a finite indexed family of upper sets generated by neighbourhoods.

Proof. Pass between a finite list and its indexing by the finite set of positions. ■

Theorem (`NeighborhoodSystem.PDmem_upSet`). The upper set generated by any neighbourhood is a powerdomain neighbourhood.

Proof. Use the singleton list of generators. ■

Theorem (`NeighborhoodSystem.PDmem_master`). The upper set generated by the master neighbourhood is a powerdomain neighbourhood.

Proof. Apply the singleton construction to the master neighbourhood. ■

Theorem (`NeighborhoodSystem.upSet_inter_nonempty_iff`). Two generated upper sets have nonempty intersection exactly when some neighbourhood is contained in the intersection of their generators.

Proof. A member of both upper sets is precisely a neighbourhood contained in both generators. ■

4.8.22 Definition 7.9 — power domain

DEFINITION 7.9. Let $\mathcal{D}$ be any neighbourhood system and define

$$\mathbb{P}\mathcal{D} = \left\{ \bigcup_{i<n} (\downarrow X_i) \mid \forall i < n.\, X_i \in \mathcal{D} \right\}.$$

We recall that for any $X \in \mathcal{D}$

$$\downarrow X = \{Y \in \mathcal{D} \mid Y \subseteq X\}.$$

The finite unions in $\mathbb{P}\mathcal{D}$ can be empty (i.e. if $n = 0$). □

Formally, the system $\mathbb{P}\mathcal{D}$ is just more or less the closure of $\mathcal{D}$ under finite unions; however, this would not be an isomorphism-invariant construct unless $\mathcal{D}$ is "prepared". The preparation consists of replacing $\mathcal{D}$ by the isomorphic domain

$$\mathcal{D}^\dagger = \{\downarrow X \mid X \in \mathcal{D}\}.$$

(In this connection refer back to Exercise 1.20.) We remark that

$$\downarrow X \cap \downarrow Y \neq \emptyset \text{ iff } \{X, Y\} \text{ is consistent in } \mathcal{D},$$

and in that case

$$\downarrow X \cap \downarrow Y = \downarrow (X \cap Y).$$

Definition_7_9.lean

@import "Definition_7_9.lean"

The development is with the power domain peer.

Theorem (`definition_79`). The dagger of a neighbourhood system is isomorphic to it, and the upper set of the master neighbourhood lies in the powerdomain.

Proof. By the powerdomain. ■

4.8.23 Effective powerdomain

The powerdomain of an effectively given neighbourhood system is effectively given.

Definition (`NeighborhoodSystem.PowerDomain`). The powerdomain neighbourhood system has finite unions of generated upper sets as neighbourhoods and the upper set of the original master neighbourhood as master.

Proof. Finite unions are closed under the required intersections and every such family lies below the master family. ■

Theorem (`NeighborhoodSystem.PowerDomain_mem`). Membership as a powerdomain neighbourhood is exactly being a finite union of upper sets generated by original neighbourhoods.

Proof. This is the defining neighbourhood predicate. ■

Theorem (`NeighborhoodSystem.PowerDomain_master`). The master powerdomain neighbourhood is the upper set generated by the original master neighbourhood.

Proof. This is the defining master. ■

Definition (`NeighborhoodSystem.UPX`). For a finite list of indices, UPX is the union of the upper sets generated by the enumerated neighbourhoods at those indices.

Theorem (`NeighborhoodSystem.UPX_def`). UPX is the finite union of the generated upper sets named by its index list.

Proof. This restates the definition. ■

Definition (`NeighborhoodSystem.Ypd`). The powerdomain neighbourhood coded by c is UPX of the finite list decoded from c.

Theorem (`NeighborhoodSystem.Ypd_def`). Decoding c and forming its finite generated union gives $Ypd(c)$.

Proof. This restates the definition. ■

Definition (`NeighborhoodSystem.innerInterStp`). For a fixed outer generator, the inner intersection step examines another generator and prepends their computed intersection exactly when the pair is consistent.

Definition (`NeighborhoodSystem.innerInterCode`). The inner intersection code folds the inner step through a coded finite list, beginning with a given accumulator.

Theorem (`NeighborhoodSystem.innerInterStp_eq`). On an explicitly packed state, the inner step either prepends the computed intersection index or leaves the accumulator unchanged, according as the consistency test returns one.

Proof. Unpack the state into the current generator, accumulator, and fixed generator. ■

Theorem (`NeighborhoodSystem.innerInterCode_eq`). The inner code equals the corresponding left fold over the decoded list.

Proof. Coded iteration agrees with list iteration, and the packed step has the preceding explicit form. ■

Theorem (`NeighborhoodSystem.mem_UPX`). A set belongs to $UPX(l)$ exactly when it belongs to the upper set of some enumerated neighbourhood whose index occurs in l.

Proof. This is membership in the finite indexed union. ■

Theorem (`NeighborhoodSystem.UPX_cons`). Adding b to the front of a list adds the upper set generated by the neighbourhood indexed by b to the union.

Proof. Split list membership between the head and tail. ■

Theorem (`NeighborhoodSystem.UPX_nil`). The union generated by the empty list is empty.

Proof. The empty list has no generator. ■

Theorem (`NeighborhoodSystem.Ypd_cons_code`). A nonzero list code obtained by prepending v codes the union of the upper set at v with the family coded by the accumulator.

Proof. Decode the cons code and apply the head-tail formula for UPX. ■

Theorem (`NeighborhoodSystem.Ypd_zero`). The zero code denotes the empty powerdomain neighbourhood.

Proof. Zero decodes to the empty list. ■

Theorem (`NeighborhoodSystem.PDmem_exists_Ypd_aux`). Every finite union generated by a list of original neighbourhoods is equal to $Ypd(c)$ for some code c.

Proof. Induct on the generator list, use surjectivity of the original presentation for the head, and prepend its index to the code for the tail. ■

Theorem (`NeighborhoodSystem.PDmem_exists_Ypd`). Every powerdomain neighbourhood has a Ypd code.

Proof. Choose its finite generator list and apply the coded-list construction. ■

Theorem (`NeighborhoodSystem.mem_Ypd`). A set belongs to $Ypd(c)$ exactly when it belongs to the upper set generated by some index in the list decoded from c.

Proof. Apply the membership characterization of UPX. ■

Theorem (`NeighborhoodSystem.Ypd_isPDmem`). Every $Ypd(c)$ is a powerdomain neighbourhood.

Proof. Map the decoded index list to its enumerated neighbourhoods; their finite union is exactly $Ypd(c)$. ■

Definition (`NeighborhoodSystem.outerInterStp`). The outer intersection step runs the inner intersection code for the current generator against the second coded list.

Definition (`NeighborhoodSystem.interCode`). The intersection code folds the outer step over the first coded list, starting with the empty code.

Theorem (`NeighborhoodSystem.outerInterStp_eq`). On an explicitly packed state, the outer step is the inner intersection code for the unpacked generator, accumulator, and second list.

Proof. This follows by unpacking the state. ■

Theorem (`NeighborhoodSystem.interCode_eq`). The intersection code is the left fold of the inner intersection operation over the decoded first list.

Proof. Coded iteration agrees with list iteration and the outer step has the preceding explicit form. ■

Theorem (`NeighborhoodSystem.primrec_innerInterStp`). If the consistency test is primitive recursive, then the inner intersection step is primitive recursive.

Proof. It is assembled from projections, pairing, the primitive-recursive intersection index, the consistency test, and numerical selection. ■

Theorem (`NeighborhoodSystem.primrec_outerInterStp`). If the consistency test is primitive recursive, then the outer intersection step is primitive recursive.

Proof. Primitive-recursive coded folding preserves primitive recursiveness. ■

Theorem (`NeighborhoodSystem.primrec_interCode`). If the consistency test is primitive recursive, then the binary intersection-code function is primitive recursive.

Proof. It is the coded fold of the primitive-recursive outer step. ■

Theorem (`NeighborhoodSystem.subCode_computable`). It is decidable whether every generator in one decoded list is contained in some generator in another decoded list.

Proof. Original-neighbourhood inclusion is decidable, and bounded existential and universal search over finite decoded lists preserves decidability. ■

Theorem (`NeighborhoodSystem.upSet_inter_eq_empty_of_not_cons`). If no enumerated neighbourhood lies inside the intersection of two enumerated neighbourhoods, then their generated upper sets are disjoint.

Proof. A member of both upper sets would be a neighbourhood inside the intersection and hence, by surjectivity, would yield a forbidden index. ■

Theorem (`NeighborhoodSystem.Ypd_innerstep`). One inner step changes the coded family by adjoining the intersection of the two generated upper sets.

Proof. In the consistent case the computed neighbourhood equals the intersection generator; in the inconsistent case the two upper sets are disjoint and the accumulator is unchanged. ■

Theorem (`NeighborhoodSystem.Ypd_innerfoldl`). Folding the inner step over a list adjoins the intersection of the fixed generator's upper set with the union generated by that list.

Proof. Induct on the list and distribute intersection over union. ■

Theorem (`NeighborhoodSystem.Ypd_innerInterCode`). The inner intersection code denotes the old accumulator union the intersection of the fixed generator's upper set with the family denoted by the input code.

Proof. Replace coded iteration by its list fold and apply the inner-fold identity. ■

Theorem (`NeighborhoodSystem.Ypd_outerfoldl`). Folding inner intersection over an outer list adjoins the intersection of the union generated by that list with the second coded family.

Proof. Induct on the outer list and distribute union over intersection. ■

Theorem (`NeighborhoodSystem.Ypd_interCode`). The intersection code of n, m denotes $Ypd(n) \cap Ypd(m)$.

Proof. Apply the outer-fold identity with the empty initial code. ■

Theorem (`NeighborhoodSystem.upSet_subset_Ypd_iff`). The upper set generated at index a is contained in $Ypd(k)$ exactly when some decoded generator of k contains the neighbourhood at a.

Proof. Test inclusion on the generator itself for one direction; transitivity proves the other. ■

Theorem (`NeighborhoodSystem.Ypd_subset_iff`). $Ypd(c) \subseteq Ypd(k)$ exactly when every decoded generator of c is contained in some decoded generator of k.

Proof. A finite union is contained in a family exactly when each summand is, then apply the generated-upper-set criterion. ■

Theorem (`NeighborhoodSystem.Ypd_eq_iff`). Two coded powerdomain neighbourhoods are equal exactly when their decoded generators mutually refine one another.

Proof. Equality is mutual inclusion, characterized in each direction by the preceding theorem. ■

Theorem (`NeighborhoodSystem.eqCode_computable`). Equality of two coded powerdomain neighbourhoods is decidable.

Proof. Decide the two finite mutual-refinement conditions. ■

Theorem (`NeighborhoodSystem.Ypd_interEq_computable`). If consistency is primitive recursive with the stated specification, the ternary relation $Ypd(n) \cap Ypd(m) = Ypd(k)$ is decidable.

Proof. Compute the intersection code and decide its equality with k. ■

Definition (`NeighborhoodSystem.PDPresentation`). The effective powerdomain presentation enumerates Ypd-families, computes intersections by the coded double fold, and uses the singleton code of the original master index as master.

Proof. Coding is surjective, equality and consistency are decidable, intersection coding is primitive recursive and correct, and the chosen master code denotes the powerdomain master. ■

Theorem (`NeighborhoodSystem.PowerDomain_isEffectivelyGiven`). The powerdomain of an effectively given neighbourhood system is effectively given.

Proof. Choose an effective presentation of the original system and its computable consistency test, then form the effective powerdomain presentation. ■

4.8.24 Proposition 7.10 — power domain effective

PROPOSITION 7.10. The power domain $\mathbb{P}\mathcal{D}$ is a neighbourhood system if $\mathcal{D}$ is, and it is effectively given if $\mathcal{D}$ is.

Proof : The system $\mathcal{D}^\dagger$ is a neighbourhood system as we just remarked; indeed it is a positive neighbourhood system. It is easy to prove that the closure of any positive system under finite unions is a neighbourhood system, because the resulting family of sets is closed under *all* finite intersections. (If we left out the empty union, the result would be a positive system.) The proof is obvious since intersection of sets distributes over finite union. So $\mathbb{P}\mathcal{D}$ is a neighbourhood system.

For the second half of the proposition, we just have to constructivize the previous argument. Thus, if

$$\mathcal{D} = \{X_n \mid n \in \mathbb{N}\},$$

then the elements of $\mathbb{P}\mathcal{D}$ can be written as:

$$\bigcup_{i<q} (\downarrow X_{n_i}),$$

and hence are indexed by the finite sequences $\langle n_0, \ldots, n_{q-1}\rangle$ of integers. Now one of the standard devices of recursion theory is to put the finite sequences of integers into a recursive one-one correspondence with the integers themselves. This is the start of the recursive presentation of $\mathbb{P}\mathcal{D}$, since it means we can list effectively all the required neighbourhoods.

Next consider an intersection

$$\bigcup_{i<q} (\downarrow X_{n_i}) \cap \bigcup_{j<r} (\downarrow X_{m_j}) = \bigcup_{\substack{i<q \\ j<r}} \downarrow (X_{n_i} \cap X_{m_j})\,.$$

Some of the terms which are $\emptyset$ have to be thrown out — but this requires only a finite number of decisions all computable by assumption. Now we have to rewrite

$$X_{n_i} \cap X_{m_j} = X_{k_{ij}}\,,$$

but the finding of k_{ij} is also computable. *Finally*, we have to re-order the doubly indexed sequence into a singly indexed sequence of length $q \cdot r$, but this is easily seen to be computable also. Therefore, intersections can be "calculated".

It remains to be shown that equality between neighbourhoods in $\mathbb{P}\mathcal{D}$ is decidable. The question really comes down to deciding something like:

$$\downarrow X_k \subseteq \bigcup_{i<q} \downarrow X_{n_i}\,.$$

Now since $X_k \in \downarrow X_k$, we find that the above is just equivalent to:

$$\exists i < q.\, X_k \subseteq X_{n_i}\,.$$

By our assumptions on $\mathcal{D}$, this is decidable. (It is this part of the argument that required the passage to $\mathcal{D}^\dagger$. It does not seem to be generally true that the closure under finite unions of an effectively given system is again effectively given.) □

One of the main reasons that $\mathbb{P}\mathcal{D}$ is like a power domain is the possibility of forming "finite sets".

The development is with the effective powerdomain peer.

Theorem (`proposition_710`). The powerdomain of an effectively given neighbourhood system is effectively given.

Proof. By the effective powerdomain presentation. ■

4.8.25 Finite powerdomain elements

Finite joins of elements, and singletons, are elements of the powerdomain.

Definition (`NeighborhoodSystem.PDfinJoinZero`). The empty powerdomain join is the least powerdomain element.

Definition (`NeighborhoodSystem.PDmemFinJoin`). A powerdomain neighbourhood belongs to the finite join of x_i when there are neighbourhoods X_i of the respective x_i whose generated upper sets are all contained in it.

Definition (`NeighborhoodSystem.PDfinJoinSucc`). For a nonempty finite family, the preceding membership condition defines a powerdomain element.

Proof. The master neighbourhood is witnessed by master neighbourhoods of all components; intersections are witnessed componentwise; and membership is upward closed. ■

Definition (`NeighborhoodSystem.PDfinJoin`). The finite join is the least element for an empty family and the nonempty finite-join element otherwise.

Theorem (`NeighborhoodSystem.PDmem_finJoinZero`). A neighbourhood belongs to the empty finite join exactly when it is the master powerdomain neighbourhood.

Proof. This is the membership rule for the least element. ■

Definition (`NeighborhoodSystem.PDsingleton`). The singleton powerdomain element is the one-term finite join.

Theorem (`NeighborhoodSystem.PDmem_finJoinSucc`). Membership in a nonempty finite join is exactly the finite-join witness condition.

Proof. This is the defining membership relation. ■

Theorem (`NeighborhoodSystem.PDmem_singleton`). A powerdomain neighbourhood belongs to the singleton generated by x exactly when it contains the upper set of some neighbourhood of x.

Proof. Specialize the nonempty finite-join condition to the unique index of a one-element family. ■

Theorem (`NeighborhoodSystem.PDmem_finJoin`). Membership in a finite join is equality with the master neighbourhood when the family is empty, and the finite-join witness condition otherwise.

Proof. Separate the zero and successor cases of the family size. ■

Theorem (`NeighborhoodSystem.PDmem_finJoin_iUnion`). For a nonempty family, membership in its finite join is equivalent to containing the union of the upper sets generated by suitable component neighbourhoods.

Proof. Containing every generated upper set is equivalent to containing their union. ■

Theorem (`NeighborhoodSystem.PDmem_down`). A powerdomain neighbourhood is downward closed among original neighbourhoods: if it contains Z, $X \subseteq Z$, and X is a neighbourhood, then it contains X.

Proof. Choose a generator whose upper set contains Z; transitivity gives that the same generator's upper set contains X. ■

4.8.26 Definition 7.11 — finite sets of elements

DEFINITION 7.11. For elements $x_0, \ldots, x_{n-1} \in |D|$ we define

$$\{x_0, \ldots, x_{n-1}\} = \{z \in \mathbb{P}D \mid \exists X_0 \in x_0 \ldots \exists X_{n-1} \in x_{n-1}.\ \bigcup_{i<n} (\uparrow X_i) \subseteq z\}.$$

(Note, we could also write $\forall i < n.\, X_i \in z$.) □

The development is with the finite powerdomain elements peer.

Theorem (`definition_711`). The singleton of an element is the finite join of that one element.

Proof. By the definition of the singleton. ■

```

4.8.27 Finite-join approximation

The singleton and binary join maps into the powerdomain are approximable, and the binary join is computable.

Theorem (`NeighborhoodSystem.PDsingleton_mono`). If $X' \subseteq X$ are neighbourhoods, then the singleton generated by the principal element at X lies below the singleton generated at X'.

Proof. Every neighbourhood containing an upper set witnessed above X is also witnessed above the smaller neighbourhood X'. ■

Definition (`NeighborhoodSystem.PDsingletonApproxMap`). The singleton approximable map sends a neighbourhood X to the singleton powerdomain element generated by the principal element at X.

Proof. The preceding antitonicity in neighbourhood refinement gives the required monotonicity of the relation. ■

Theorem (`NeighborhoodSystem.PDsingletonApproxMap_rel`). For a neighbourhood X, the singleton map relates X to W exactly when W belongs to the singleton generated by the principal element at X.

Proof. This is the relation induced by the monotone assignment. ■

Definition (`NeighborhoodSystem.PDsingletonMeet`). The meet of two powerdomain elements consists of the neighbourhoods belonging to both.

Proof. Common membership is closed under intersection and enlargement and contains the master neighbourhood. ■

Theorem (`NeighborhoodSystem.PDsingletonMeet_mem`). A neighbourhood belongs to the singleton meet of a and b exactly when it belongs to both a and b.

Proof. This is the defining membership condition. ■

Definition (`NeighborhoodSystem.PDfinJoinApproxMap2`). The binary finite-join relation holds when each input is related to the target by the singleton approximable map.

Proof. Domain and codomain validity, target intersections, and monotonicity hold componentwise. ■

Definition (`NeighborhoodSystem.finJoinMap_prod`). The product form of the binary finite-join map is obtained by viewing the binary relation as an approximable map out of the product system.

Theorem (`NeighborhoodSystem.finJoinMap_prod_rel`). On a product neighbourhood generated by X, Y, the product join relation is exactly the binary finite-join relation on X, Y.

Proof. The two product preimages are precisely X and Y. ■

Theorem (`NeighborhoodSystem.PDext`). Two powerdomain elements are equal when they have the same neighbourhoods.

Proof. Elements of any neighbourhood system are determined extensionally by membership. ■

Theorem (`NeighborhoodSystem.PDfinJoinApproxMap2_rel_iff`). The binary finite-join relation holds exactly when both singleton relations hold.

Proof. This is its defining condition. ■

Theorem (`NeighborhoodSystem.PDfinJoin_pair`). The two-term finite join of x, y is the meet of their singleton powerdomain elements.

Proof. Both sides contain exactly those powerdomain neighbourhoods that contain suitable generated upper sets for both x and y. ■

Theorem (`NeighborhoodSystem.PDfinJoin_inter_two`). A neighbourhood belongs to the two-term finite join exactly when it belongs to each singleton.

Proof. Combine the two-term join identity with the membership rule for the singleton meet. ■

Theorem (`NeighborhoodSystem.PDfinJoinApproxMap2_rel_PD`). On neighbourhoods X, Y, the binary relation to W holds exactly when W belongs to the two-term join of the corresponding principal elements.

Proof. Each conjunct is singleton membership for one principal element, and two-term join membership is their conjunction. ■

Theorem (`NeighborhoodSystem.PDsingletonApproxMap_rel_Ypd_iff`). The singleton map relates the neighbourhood indexed by n to the coded powerdomain neighbourhood k exactly when some index in the decoded list for k names a neighbourhood containing the one indexed by n.

Proof. Membership of the generator in the coded finite union selects exactly such a list entry. ■

Theorem (`NeighborhoodSystem.PDsingletonApproxMap_toElementMap`). The element map induced by the singleton approximable map sends x to its singleton powerdomain element.

Proof. A witness neighbourhood below x can be enlarged within x, and conversely a singleton witness itself supplies a source neighbourhood. ■

Theorem (`NeighborhoodSystem.PDfinJoinApproxMap2_toElementMap`). The element map induced by the binary finite-join relation sends x, y to their two-term powerdomain join.

Proof. Binary relation membership splits into the two singleton images, whose conjunction is two-term join membership. ■

Theorem (`NeighborhoodSystem.PDsingleton_principal`). The singleton of a principal element generated by X equals the principal powerdomain element generated by the upper set of X.

Proof. On both sides, membership means being a powerdomain neighbourhood containing that generated upper set. ■

Theorem (`NeighborhoodSystem.ext_of_principal`). Two approximable maps are equal if their element maps agree on every principal element.

Proof. A relation at X is equivalent to target membership in the image of the principal element at X. ■

Theorem (`NeighborhoodSystem.finJoinMap_prod_toElementMap`). The product join map sends a pair of elements to their two-term powerdomain join.

Proof. Convert the product map to its binary form and apply the binary element-map identity. ■

Theorem (`NeighborhoodSystem.singleton_isComputable`). Relative to the effective powerdomain presentation, the singleton approximable map is computable.

Proof. Its indexed relation is the decidable bounded search for a decoded generator containing the source neighbourhood. ■

Theorem (`NeighborhoodSystem.PDfinJoinApproxMap2_isComputable`). The product form of the binary finite-join map is computable.

Proof. Its relation is the conjunction of two computable singleton relations after primitive-recursively selecting the two product coordinates. ■

4.8.28 V-shape counterexample

The V-shaped neighbourhood system does not embed into its powerdomain.

Definition (`Counterexample712C.HasTop`). A neighbourhood system has a top element when some element lies above every element in its domain order.

Theorem (`Counterexample712C.ft_inter`). The singleton sets containing false and true have empty intersection.

Proof. No Boolean value is simultaneously false and true. ■

Definition (`Counterexample712C.improperTop`). If the neighbourhoods of a system are closed under arbitrary binary intersections, the family of all neighbourhoods forms an element of that system.

Proof. Closure gives finite-intersection closure, while the remaining element conditions follow directly from neighbourhood membership. ■

Theorem (`Counterexample712C.tf_inter`). The singleton sets containing true and false have empty intersection.

Proof. No Boolean value is simultaneously true and false. ■

Definition (`Counterexample712C.Vshape`). The V-shaped system on the Booleans has exactly three neighbourhoods: the whole set and the two singleton sets.

Proof. The whole set is master; the only incompatible intersection is empty, which cannot contain any of the three nonempty neighbourhoods required by the intersection axiom. ■

Theorem (`Counterexample712C.Vshape_mem_false`). The singleton containing false is a V-shaped neighbourhood.

Proof. It is one of the three defining neighbourhoods. ■

Theorem (`Counterexample712C.Vshape_mem_true`). The singleton containing true is a V-shaped neighbourhood.

Proof. It is one of the three defining neighbourhoods. ■

Theorem (`Counterexample712C.Vshape_not_mem_empty`). The empty set is not a V-shaped neighbourhood.

Proof. It is neither the whole Boolean set nor either Boolean singleton. ■

Theorem (`Counterexample712C.Vshape_not_hasTop`). The V-shaped domain has no top element.

Proof. A top element would contain both singleton neighbourhoods and hence their empty intersection, forcing the empty set to be a neighbourhood of that element, contrary to the V-shaped neighbourhood list. ■

Theorem (`Counterexample712C.hasTop_of_inter_closed`). A neighbourhood system whose neighbourhoods are closed under binary intersection has a top element.

Proof. The element consisting of all neighbourhoods lies above every other element. ■

Theorem (`Counterexample712C.hasTop_of_iso`). Having a top element is preserved when transported backwards along an order isomorphism.

Proof. The inverse image of a top element is above every element by order reflection. ■

Theorem (`Counterexample712C.powerDomain_hasTop`). Every powerdomain has a top element.

Proof. Powerdomain neighbourhoods are closed under intersection, so the intersection-closed construction applies. ■

Theorem (`Counterexample712C.subsystem_inter_closed`). A subsystem of an intersection-closed neighbourhood system is itself intersection closed.

Proof. The ambient intersection is a neighbourhood, and the subsystem's closure property brings it back into the subsystem. ■

Theorem (`Counterexample712C.hasTop_of_trianglelefteq_powerDomain`). Any neighbourhood system isomorphic to a subsystem of a powerdomain has a top element.

Proof. The subsystem inherits intersection closure from the powerdomain and therefore has a top, which the isomorphism transports to the original system. ■

Theorem (`Counterexample712C.vshape_not_trianglelefteq_powerDomain`). The V-shaped neighbourhood system is not isomorphic to any subsystem of its powerdomain.

Proof. Such an embedding would give the V-shaped domain a top element, contradicting its failure to have one. ■

4.8.29 Proposition 7.12 — finite sets are approximable

PROPOSITION 7.12. The mapping

$$\lambda x_0, \ldots, x_{n-1}. \{x_0, \ldots, x_{n-1}\} : D^n \to \mathbb{P}D$$

is approximable and is computable if D is effectively given. Moreover, the map $\lambda x. \{x\}$ shows that $D \trianglelefteq \mathbb{P}D$, and we also have the law:

$$\{x_0, \ldots, x_{n-1}\} = \{x_0\} \cap \cdots \cap \{x_{n-1}\}$$

as an intersection of filters.

Proof : The second part shows that everything reduces to $\lambda x. \{x\}$. We see that

$$X_k \ (\lambda x. \{x\}) \bigcup_{i<q} (\uparrow X_{n_i}) \text{ iff } \exists i < q. X_k \sqsubseteq X_{n_i}.$$

Thus, $\lambda x. \{x\}$ is an approximable mapping and is computable in the effectively given case.

The proof of the law can be reduced to the special case

$$\{x\} \cap \{y\} = \{x, y\}$$

for the sake of illustration. In terms of finite elements of the two domains D and $\mathbb{P}D$ we find

$$\{\uparrow X\} = \uparrow\uparrow X,$$

and so,

$$\begin{aligned} \{\uparrow X\} \cap \{\uparrow Y\} &= \uparrow\uparrow X \cap \uparrow\uparrow Y \\ &= \uparrow (\uparrow X \cup \uparrow Y) \\ &= \{\uparrow X, \uparrow Y\}. \end{aligned}$$

An equation between approximable functions that checks for finite elements also holds for all elements.

Finally, we note that

$$D \cong D^\dagger \trianglelefteq \mathbb{P}D$$

and that the isomorphism involved is just $\lambda x. \{x\}$ by what we saw on the finite elements. □

Further combinators on the power domain are given in the exercises.

The development is with the finite-join approximation and V-shape counterexample peers.

Theorem (`proposition_712`). Binary join into the powerdomain is the meet of the two singletons and is computable, and the V-shaped system does not embed into its powerdomain.

Proof. By the finite-join approximation and the V-shape counterexample. ■

4.8.30 Lecture VII exercises

EXERCISES

4.8.31 Inclusion structures

An inclusion structure on the integers determines a neighbourhood system, and every computable presentation reconstructs its system.

Definition (`InclStructure`). An inclusion structure is a reflexive and transitive recursive relation on natural numbers, equipped with a greatest index and a primitive-recursive operation choosing meets whenever two indices are consistent; consistency and the universal property of a proposed meet are recursively decidable.

Definition (`InclStructure.CONS`). Two indices are consistent when some index is included in both.

Definition (`InclStructure.MEET`). An index is a meet of two others when the indices included in it are exactly those included in both.

Definition (`InclStructure.toNbhd`). The neighbourhood represented by an index is the set of all indices included in it.

Theorem (`InclStructure.mem_toNbhd`). An index belongs to the neighbourhood represented by another exactly when it is included in that index.

Proof. This is the defining membership condition. ■

Theorem (`InclStructure.toNbhd_inter_eq_iff`). The intersection of two represented neighbourhoods equals a third represented neighbourhood exactly when the third index is their meet.

Proof. Extensional equality says that every index belongs to the third neighbourhood exactly when it belongs to both of the first two. ■

Theorem (`InclStructure.toNbhd_subset_iff`). One represented neighbourhood is included in another exactly when its representing index is included in the other index.

Proof. The forward direction applies inclusion to the reflexive member; the reverse direction uses transitivity. ■

Theorem (`InclStructure.toNbhd_subset_inter_iff`). A represented neighbourhood lies below an intersection exactly when its index is included in both indices.

Proof. Inclusion in an intersection is equivalent to the conjunction of the two inclusions. ■

Theorem (`InclStructure.toNbhd_top`). The neighbourhood represented by the greatest index is the whole set of indices.

Proof. Every index is included in the greatest index. ■

Definition (`InclStructure.toSystem`). An inclusion structure determines the neighbourhood system whose neighbourhoods are precisely its represented sets and whose master is the whole set of indices.

Theorem (`InclStructure.toSystem_mem`). A set is a neighbourhood of the induced system exactly when it is represented by some index.

Proof. This is the defining neighbourhood predicate. ■

Theorem (`meet_iff_interEq`). In a computable presentation, the universal lower-bound property for three numbered neighbourhoods is equivalent to equality of the intersection of the first two with the third.

Proof. Equality immediately gives the lower-bound property. Conversely, choose a numbered representative of the intersection and compare it with the proposed meet in both directions. ■

Definition (`ofPresentation`). A computable presentation determines an inclusion structure by ordering indices according to inclusion of their numbered neighbourhoods, using the presentation's intersection and master indices.

Theorem (`ofPresentation_INCL`). Inclusion in the structure obtained from a presentation is exactly inclusion between the corresponding numbered neighbourhoods.

Proof. This is the defining relation. ■

Theorem (`mem_ofPresentation_toNbhd`). An index belongs to the reconstructed neighbourhood of n exactly when its numbered neighbourhood is included in the neighbourhood numbered by n.

Proof. Expand the two defining membership relations. ■

Theorem (`ofPresentation_toNbhd_eq_iff`). Two reconstructed neighbourhoods are equal exactly when their original numbered neighbourhoods are equal.

Proof. Both equalities are characterized by mutual inclusion. ■

Definition (`reconstruct`). The reconstruction of a computable presentation is the neighbourhood system induced by its inclusion structure.

Definition (`reconElem`). An original element yields a reconstructed element containing a represented index-set exactly when the original element contains the corresponding numbered neighbourhood.

Definition (`reconElemInv`). A reconstructed element yields an original element containing a neighbourhood exactly when some equal numbered neighbourhood has its represented index-set in the reconstructed element.

Definition (`reconIso`). The preceding two transformations form an order isomorphism between the original elements and the reconstructed elements.

Definition (`InclStructure.toPresentation`). The induced neighbourhood system has a computable presentation given by the represented neighbourhoods, the structure's meet operation, and its greatest index.

Theorem (`InclStructure.axiom_i`). Every index is included in itself.

Proof. This is reflexivity of the inclusion structure. ■

Theorem (`InclStructure.axiom_ii`). Inclusion of indices is transitive.

Proof. This is transitivity of the inclusion structure. ■

Theorem (`InclStructure.axiom_iii`). There is an index above every index.

Proof. The greatest index has this property. ■

Theorem (`InclStructure.axiom_iv`). Every consistent pair of indices has a meet.

Proof. The designated meet index satisfies the meet specification whenever consistency has a witness. ■

Theorem (`ofPresentation_toPresentation_INCL`). Passing from an inclusion structure to its presentation and back preserves the original inclusion relation.

Proof. Inclusion between represented neighbourhoods is equivalent to inclusion between their indices. ■

Theorem (`reconstruct_isomorphic`). The reconstruction of a computable presentation is isomorphic to its original neighbourhood system.

Proof. Use the inverse order isomorphism between original and reconstructed elements. ■

Theorem (`InclStructure.toSystem_isEffectivelyGiven`). The neighbourhood system induced by an inclusion structure is effectively given.

Proof. Its represented neighbourhoods carry the computable presentation constructed above. ■

4.8.32 Exercise 7.13 — axiomatic neighbourhood structure

Show that an effectively given domain can always be identified with a relation $\mathrm{INCL}(n, m)$ on integers, where the two derived relations

$$\mathrm{CONS}(n, m) \text{ iff } \exists k.\, \mathrm{INCL}(k, n) \text{ and } \mathrm{INCL}(k, m);$$

$$\mathrm{MEET}(n, m, k) \text{ iff } \forall j\, [\mathrm{INCL}(j, k) \text{ iff } \mathrm{INCL}(j, n) \text{ and } \mathrm{INCL}(j, m)]$$

are both recursively decidable, and where the following axioms hold:

(i) $\forall n.\, \mathrm{INCL}(n, n)$;

(ii) $\forall n, m, k.\, \mathrm{INCL}(n, m)$ and $\mathrm{INCL}(m, k)$ imply $\mathrm{INCL}(n, k)$;

(iii) $\exists m\, \forall n.\, \mathrm{INCL}(n, m)$

(iv) $\forall n, m.\, \mathrm{CONS}(n, m)$ implies $\exists k.\, \mathrm{MEET}(n, m, k)$.

(Hint: Consider the neighbourhood system

$$\mathcal{D} = \big\{\{m \in \mathbf{N} \mid \mathrm{INCL}(m, n)\} \mid n \in \mathbf{N}\big\}.$$

Is this essentially any effectively given system?)

The development is with the inclusion structures peer.

Theorem (`example_713`). Every computable presentation reconstructs a system isomorphic to the original, and every inclusion structure is effectively given.

Proof. By the reconstruction isomorphism and the presentation of an inclusion structure. ■

4.8.33 Computable witnesses

A computable element is the decreasing union of the principal elements named by a primitive-recursive sequence of indices.

Definition (`ComputableWitness.tFun`). From a sequence of presentation indices, form a new sequence by taking the first index initially and then repeatedly choosing an index for the intersection with the next neighbourhood.

Theorem (`ComputableWitness.repred_exists_primrec_range`). Every nonempty recursively enumerable predicate on the natural numbers is the range of a primitive-recursive function.

Proof. Enumerate witnesses to the predicate and return a fixed known witness whenever the current search certificate fails. ■

Theorem (`ComputableWitness.tFun_zero`). The initial value of the thinning sequence is the initial value of the original sequence.

Proof. This is the initial clause of the recursion. ■

Theorem (`ComputableWitness.tFun_succ`). Each successor value of the thinning sequence is the chosen intersection index of its preceding value and the next original value.

Proof. This is the successor clause of the recursion. ■

Theorem (`ComputableWitness.primrec_tFun`). Thinning a primitive-recursive sequence along a computable presentation produces a primitive-recursive sequence.

Proof. Primitive recursion applies because the presentation's intersection-index operation and the original sequence are primitive recursive. ■

Theorem (`ComputableWitness.computableElement_eq_decreasing_iUnion_principal`). Every computable element is generated by a primitive-recursive decreasing sequence of principal elements: a neighbourhood belongs to the element exactly when it belongs to one of those principals.

Proof. Enumerate the indices of neighbourhoods containing the element, starting with a master index, and thin this enumeration by successive intersections. Every original neighbourhood occurs above the corresponding thinned neighbourhood, while every thinned neighbourhood still contains the element. ■

Theorem (`ComputableWitness.repred_range_primrec`). The range of a primitive-recursive function is recursively enumerable.

Proof. A number belongs to the range exactly when some coded pair has first component mapped to its second component. ■

Theorem (`ComputableWitness.repred2_exists_primrec_enum`). Every inhabited recursively enumerable binary relation has a primitive-recursive enumeration by two coordinate functions.

Proof. Enumerate the paired relation by one primitive-recursive function and take the two projections of each value. ■

Theorem (`NeighborhoodSystem.PDmem_upSet_inter`). The intersection of the upper sets generated by two neighbourhoods is a power-domain neighbourhood.

Proof. It is the upper set of their intersection when that intersection is a neighbourhood, and is empty otherwise; both forms are power-domain neighbourhoods. ■

Theorem (`NeighborhoodSystem.upSetUnion_cons`). The union of upper sets indexed by a list with head Y is the union of the upper set of Y and the union indexed by the tail.

Proof. Split membership in the list according to whether the chosen entry is the head or lies in the tail. ■

Theorem (`NeighborhoodSystem.upSetUnion_nil`). The union of upper sets indexed by the empty list is empty.

Proof. The empty list has no indexing member. ■

Theorem (`NeighborhoodSystem.PDmem_upSet_inter_biUnion`). The intersection of one principal upper set with any finite union of principal upper sets is a power-domain neighbourhood.

Proof. Induct on the list and distribute intersection over union, using closure under binary union. ■

Theorem (`NeighborhoodSystem.PDmem_biUnion_inter`). The intersection of a finite union of principal upper sets with any power-domain neighbourhood is a power-domain neighbourhood.

Proof. Induct on the first finite list and use the preceding principal-intersection result. ■

Theorem (`NeighborhoodSystem.PDmem_inter`). Power-domain neighbourhoods are closed under intersection.

Proof. Represent the first neighbourhood as a finite union of principal upper sets and apply the preceding theorem. ■

4.8.34 Exercise 7.14 — primitive recursive witnesses

(For recursive-function theorists.) Prove the statements after definition 7.2 about the existence of primitive recursive functions for showing things recursively enumerable. (Recall that a non-empty set is r.e. iff it

is the range of a primitive recursive function.) Show also that every computable element $y \in |E|$ can be written

$$y = \bigcup \{\uparrow Y_{t(i)} \mid i \in \mathbf{N}\},$$

where $t : \mathbf{N} \to \mathbf{N}$ is primitive recursive and where we may assume
$Y_{t(i+1)} \subseteq Y_{t(i)}$
for all $i \in \mathbf{N}$.

The development is with the computable witnesses peer.

Theorem (`example_714`). A computable element is the decreasing union of principal elements along a primitive-recursive sequence of indices.

Proof. By the computable witness. ■

4.8.35 Scott presentation

A Scott presentation records intersection equality and consistency as recursively decidable relations.

Definition (`ScottPresentation`). A Scott presentation of a neighbourhood system is a surjective numbering of its neighbourhoods for which equality of a numbered intersection with a third numbered neighbourhood, and the existence of a numbered neighbourhood below two given ones, are recursively decidable.

Definition (`ComputableMapS`). An approximable map between Scott-presented systems is computable when the relation between pairs of numbered basic neighbourhoods is recursively enumerable.

Definition (`NeighborhoodSystem.IsEffectivelyGivenS`). A neighbourhood system is effectively given in the Scott sense when it admits a Scott presentation.

Definition (`ScottPresentation.inclShuffle`). The inclusion shuffle sends a pair of indices (n, m) to the triple (n, m, n).

Theorem (`ScottPresentation.primrec_inclShuffle`). The inclusion shuffle is primitive recursive.

Proof. Pairing, both projections, and their compositions are primitive recursive. ■

Theorem (`ScottPresentation.incl_computable`). Inclusion between numbered neighbourhoods of a Scott presentation is recursively decidable.

Proof. The inclusion $X_n \subseteq X_m$ is equivalent to $X_n \cap X_m = X_n$, an instance of decidable intersection equality. ■

Definition (`ScottPresentation.swapPair`). The pair-swap operation sends (n, m) to (m, n).

Theorem (`ScottPresentation.primrec_swapPair`). Pair-swap is primitive recursive.

Proof. It is obtained by pairing the second and first projections. ■

Theorem (`ScottPresentation.eq_computable`). Equality between numbered neighbourhoods of a Scott presentation is recursively decidable.

Proof. Two sets are equal exactly when each is included in the other, and both inclusions are decidable. ■

Definition (`ComputablePresentation.toScott`). Every computable presentation has an underlying Scott presentation with the same numbering and decision procedures.

Theorem (`NeighborhoodSystem.IsEffectivelyGiven.toS`). Every effectively given neighbourhood system is effectively given in the Scott sense.

Proof. Forget the chosen intersection index and master index from a computable presentation. ■

4.8.36 Effective smash

The smash product is enumerated by pairing neighbourhoods, collapsing a factor that is the master, and its combinators are computable.

Definition (`smashEnum`). A paired index enumerates the product neighbourhood of its two components when both are proper; otherwise it enumerates the smash master neighbourhood.

Theorem (`smashEnum_master`). If at least one indexed component is the master neighbourhood, the smash enumeration returns the smash master.

Proof. The proper-pair condition fails in the defining alternative. ■

Theorem (`smashEnum_proper`). If both indexed components are proper, the smash enumeration returns their product neighbourhood.

Proof. The proper-pair condition holds in the defining alternative. ■

Theorem (`smashEnum_eq_eff`). Given Boolean characteristic functions for proper component neighbourhoods, the smash enumeration is the product of the selected component indices, where a failed properness test selects the appropriate master index.

Proof. If both tests succeed, both original indices are selected; if either fails, both selections yield master neighbourhoods and hence the smash master. ■

Theorem (`smashEnum_eq_prodNbhd_mem`). Every enumerated smash neighbourhood is a product neighbourhood of two component neighbourhoods.

Proof. Use the indexed components in the proper case and the two masters otherwise. ■

Theorem (`smashEnum_mem`). Every set in the smash enumeration is a smash neighbourhood.

Proof. A proper pair gives a proper smash neighbourhood, while every improper pair gives the master. ■

Theorem (`smashEnum_subset_master`). Every enumerated smash neighbourhood is included in the product of the component masters.

Proof. Every neighbourhood is included in the smash master, which is that product. ■

Theorem (`proper0_dec`). Properness of a numbered neighbourhood in the first component is recursively decidable.

Proof. Equality with the numbered master is decidable, so its negation is decidable. ■

Theorem (`proper1_dec`). Properness of a numbered neighbourhood in the second component is recursively decidable.

Proof. Equality with the numbered master is decidable, so its negation is decidable. ■

Definition (`smashPresentation`). The smash Scott presentation uses the smash enumeration and decides intersection equality and consistency by reducing them to the corresponding component relations and properness tests.

Theorem (`smashPresentation_X`). The neighbourhood numbered by an index in the smash presentation is its smash-enumerated neighbourhood.

Proof. This is the presentation's defining enumeration. ■

Definition (`smashProj0`). The first smash projection relates W to X when both are neighbourhoods and the left preimage of W is included in X.

Theorem (`smashProj0_rel`). The relation of the first smash projection is exactly the stated neighbourhood and left-preimage inclusion condition.

Proof. This is its defining relation. ■

Definition (`smashProj1`). The second smash projection relates W to Y when both are neighbourhoods and the right preimage of W is included in Y.

Theorem (`smashProj1_rel`). The relation of the second smash projection is exactly the stated neighbourhood and right-preimage inclusion condition.

Proof. This is its defining relation. ■

Definition (`smashPaired`). Pairing two approximable maps relates a source neighbourhood to the smash master automatically, and to a proper product neighbourhood when the two maps relate it to the respective factors.

Theorem (`smashPaired_rel`). The relation of smash pairing is precisely the disjunction between the master case and the proper componentwise case.

Proof. This is its defining relation. ■

Definition (`smashMap`). Two approximable maps act componentwise on smash products, with every source related to the target master and proper products related through the two component maps.

Theorem (`smashMap_isComputable`). The componentwise smash map of two computable maps is computable.

Proof. Proper target pairs reduce the relation to the two recursively enumerable component relations after primitive-recursive index selection; an improper target is always related. ■

Theorem (`smashPaired_isComputable`). Smash pairing of two computable maps is computable.

Proof. For a proper target pair the relation is the conjunction of the two component relations; for the target master it holds automatically. ■

Theorem (`smashProj0_isComputable`). The first smash projection is computable.

Proof. On enumerated neighbourhoods its relation is decidable inclusion of the effectively selected left component into the target neighbourhood. ■

Theorem (`smashProj1_isComputable`). The second smash projection is computable.

Proof. On enumerated neighbourhoods its relation is decidable inclusion of the effectively selected right component into the target neighbourhood. ■

Theorem (`smash_isEffectivelyGivenS`). The smash product of two effectively given systems is effectively given in the Scott sense.

Proof. Choose presentations of both factors and use their smash presentation. ■

4.8.37 Coalesced sum

The coalesced sum of effectively given neighbourhood systems is effectively given, and its injections and projections are computable.

Definition (`osum`). For systems whose neighbourhoods are nonempty, the coalesced sum has as neighbourhoods the common master and the proper neighbourhoods injected from either summand.

Theorem (`osum_master`). The master of the coalesced sum is the common sum master.

Proof. This is part of the defining structure. ■

Definition (`osumEnum`). A tagged index enumerates a proper left neighbourhood for tag zero, a proper right neighbourhood for tag one, and the common master otherwise.

Theorem (`osumEnum_left`). A zero-tagged proper left index enumerates its left injection.

Proof. The first defining alternative applies. ■

Theorem (`osumEnum_master`). If neither the left nor right tagged properness condition holds, the enumeration returns the common master.

Proof. Both proper alternatives fail. ■

Theorem (`osumEnum_right`). A one-tagged proper right index enumerates its right injection.

Proof. The left alternative is incompatible with tag one, and the right alternative applies. ■

Theorem (`osumEnum_mem`). Every enumerated set is a coalesced-sum neighbourhood.

Proof. It is either a proper injected neighbourhood or the master. ■

Theorem (`osumEnum_nonempty`). Every enumerated coalesced-sum neighbourhood is nonempty.

Proof. Injected neighbourhoods inherit nonemptiness from their summands, and the master contains the common bottom point. ■

Theorem (`osumEnum_subset_master`). Every enumerated neighbourhood is included in the common sum master.

Proof. Every neighbourhood of a neighbourhood system lies below its master. ■

Definition (`osumOutMap0`). The left projection relates a sum neighbourhood W to X when the left part of W is included in X.

Definition (`osumOutMap1`). The right projection relates a sum neighbourhood W to Y when the right part of W is included in Y.

Definition (`osumPresentation`). The coalesced-sum Scott presentation uses the tagged enumeration and decides intersections and consistency from tags, properness, and the two component presentations.

Theorem (`osumPresentation_X`). The neighbourhood numbered by an index in the coalesced-sum presentation is its tagged enumerated set.

Proof. This is the presentation's defining enumeration. ■

Theorem (`osum_eq_master_of_inj0master`). A coalesced-sum neighbourhood containing the injection of the entire left master must be the common master.

Proof. A proper left injection would force its source to equal the left master, and a right injection cannot contain a point from the nonempty left master. ■

Definition (`osumInMap0`). The left injection map relates X to W when the injection of X is included in W.

Theorem (`osum_eq_master_of_inj1master`). A coalesced-sum neighbourhood containing the injection of the entire right master must be the common master.

Proof. This is the symmetric argument using nonemptiness of the right master. ■

Definition (`osumInMap1`). The right injection map relates Y to W when the injection of Y is included in W.

Theorem (`osum_mem_subset_inj0`). A coalesced-sum neighbourhood included in a left injection is itself the injection of a proper left neighbourhood.

Proof. The master contains the common point and a right injection contains a right point, so neither can lie in a left injection. ■

Theorem (`osum_mem_subset_inj1`). A coalesced-sum neighbourhood included in a right injection is itself the injection of a proper right neighbourhood.

Proof. The symmetric exclusions leave only the proper right case. ■

Definition (`osumMap`). Two approximable maps act componentwise on coalesced sums: every source relates to the target master, while proper left and right targets are related through the corresponding map and matching source tag.

Theorem (`osumInMap0_isComputable`). The left injection map is computable.

Proof. A proper left target reduces the relation to decidable component inclusion; a proper right target is impossible, and the master case always holds. ■

Theorem (`osumInMap1_isComputable`). The right injection map is computable.

Proof. A proper right target reduces the relation to decidable component inclusion; the remaining cases are decided by their tags. ■

Theorem (`osumMap_isComputable`). The componentwise map between coalesced sums of two computable maps is computable.

Proof. The target tag decides whether the relation is automatic at the master or reduces to the recursively enumerable relation of the matching component, together with decidable source and target properness. ■

Theorem (`osumOutMap0_isComputable`). The left projection from the coalesced sum is computable.

Proof. A proper left source uses decidable inclusion of its component; right and master sources contribute the left master, whose inclusion is also decidable. ■

Theorem (`osumOutMap1_isComputable`). The right projection from the coalesced sum is computable.

Proof. This is the symmetric tag analysis for the right component. ■

Theorem (`osum_isEffectivelyGivenS`). The coalesced sum of two effectively given systems with nonempty neighbourhoods is effectively given in the Scott sense.

Proof. Choose component presentations and form the coalesced-sum presentation. ■

Theorem (`osum_mem_iff`). A set is a coalesced-sum neighbourhood exactly when it is the common master, a proper injected left neighbourhood, or a proper injected right neighbourhood.

Proof. This is the defining classification of neighbourhoods. ■

4.8.38 Effective iterate

The iterate of an effectively given neighbourhood system is effectively given.

Definition (`iterIdx`). The j-th index represented by a finite code t is its j-th list entry, with the master index used beyond the list.

Definition (`iterEnum`). The neighbourhood enumerated by t in the iterate consists of pairs (j, a) for which a belongs to the neighbourhood indexed by the j-th entry of t.

Theorem (`fiber_iterEnum`). The j-th fibre of the neighbourhood enumerated by t is the neighbourhood indexed by the j-th entry of t.

Proof. This is immediate from the definition of the enumeration. ■

Theorem (`exists_list_fiber`). For every iterate neighbourhood and every length N, its first N fibres can be represented by a list of N presentation indices.

Proof. Choose an index for each successive fibre using surjectivity of the presentation and append it to the list. ■

Definition (`interG`). At a fibre number, the intersection-index function returns the chosen index for the intersection of the two fibre neighbourhoods encoded by a pair of list codes.

Theorem (`iterIdx_ge`). At every position at least the length bound represented by a code, the iterated index is the master index.

Proof. The decoded list has length at most its code, so lookup beyond that bound returns the default. ■

Theorem (`iterEnum_inter_eq_iff`). An intersection of two enumerated iterate neighbourhoods equals a third exactly when the corresponding fibre intersections agree below the sum of the three codes.

Proof. Equality implies equality of every fibre. Conversely, above the stated bound all three fibres are master neighbourhoods, so the finite family of equalities determines the whole set. ■

Theorem (`iterEnum_mem`). Every enumerated iterate set is an iterate neighbourhood.

Proof. Each fibre is a presented neighbourhood, and all fibres beyond the code are the master neighbourhood. ■

Definition (`iterInter`). The intersection code for two iterate indices tabulates their fibrewise intersection indices up to the sum of the two codes.

Theorem (`iterInter_idx_ge`). At positions at least the sum of the two input codes, the intersection code yields the master index.

Proof. Tabulation uses the master index beyond its finite bound. ■

Theorem (`iterInter_idx_lt`). Below the sum of the two input codes, the intersection code yields the chosen intersection index of the two corresponding fibres.

Proof. Finite tabulation agrees with its generating function below the bound. ■

Theorem (`iterEnum_cons_iff`). Two enumerated iterate neighbourhoods have a common numbered refinement exactly when each fibre below the sum of their codes has a common numbered refinement.

Proof. A global refinement gives fibrewise refinements. Conversely, the fibrewise intersection code is a global refinement, with master fibres beyond the finite bound. ■

Theorem (`primrec_iterIdx_proj`). If a code-valued function is primitive recursive, then looking up the position supplied by the first projection in that code is primitive recursive.

Proof. Coded-list lookup is primitive recursive and is closed under composition. ■

Theorem (`primrec_interG`). The fibrewise intersection-index function is primitive recursive.

Proof. Both coded lookups are primitive recursive, as is the presentation's intersection-index operation. ■

Definition (`iterPresentation`). The iterate presentation enumerates finite sequences of basic neighbourhoods, computes intersections fibrewise, and uses the empty code for the master neighbourhood.

Theorem (`iterPresentation_X`). The neighbourhood numbered by t in the iterate presentation is the set enumerated by t.

Proof. This is the defining enumeration of the presentation. ■

Theorem (`iterSys_isEffectivelyGiven`). The iterate of an effectively given neighbourhood system is effectively given.

Proof. Apply the iterate construction to a chosen computable presentation. ■

Theorem (`projN_isComputable`). Projection from an iterate to its n-th coordinate is a computable approximable map.

Proof. On numbered neighbourhoods its relation is inclusion from the n-th decoded fibre into the target neighbourhood; this is recursively decidable. ■

4.8.39 Exercise 7.15 — further constructs effective

Finish the proof of 7.4 and establish similar results for the constructs $(D_0 \otimes D_1)$, $(D_0 \oplus D_1)$ and D^∞. Take into account the various appropriate combinators.

The development is with the Scott presentation, effective smash, coalesced sum, and effective iterate peers.

Theorem (`example_715`). The iterate, the coalesced sum, and the smash product of effectively given neighbourhood systems are effectively given.

Proof. By the effective iterate, the coalesced sum, and the effective smash. ■

4.8.40 Curry enumeration

Currying is a computable map of function spaces, and its neighbourhood relation is decidable.

Theorem (`curryComb_rel_recDecidable`). For compatible effective presentations of the uncurried and curried function spaces, the relation of the currying combinator on numbered neighbourhoods is recursively decidable.

Proof. Membership in a curried function neighbourhood reduces to finitely many guarded inclusion tests between numbered uncurried function neighbourhoods. The guards and finite-list quantifiers are decidable, and all index transformations are primitive recursive. ■

Theorem (`curryComb_isComputable`). Given computable presentations of three systems, there are computable presentations of the corresponding uncurried and curried function spaces for which currying is computable.

Proof. Construct the function-space presentations from recursive consistency and inclusion witnesses. The preceding decision theorem supplies the recursively enumerable relation required for currying. ■

Theorem (`toApproxMap_principal_mem`). The approximable map represented by the principal element of a function-space neighbourhood belongs to that neighbourhood.

Proof. A function-space neighbourhood is generated by finitely many steps. The represented map satisfies every generating step by the defining universal property of the principal element. ■

Theorem (`curryComb_rel`). The currying combinator relates function-space neighbourhoods G and H exactly when both are neighbourhoods and every map in G has its curry in H.

Proof. The principal map of G lies in G, and every other member lies above it. Monotonicity of currying and upward closure of H convert the principal-map condition into the stated universal condition. ■

4.8.41 Exercise 7.16 — curry as an enumeration

Let $D_0 = \{X_n \mid n \in \mathbf{N}\}$, $D_1 = \{Y_m \mid m \in \mathbf{N}\}$ and $D_2 = \{Z_k \mid k \in \mathbf{N}\}$ be three effectively given domains. Complete the proof of 7.5 by writing out curry as a relation between neighbourhoods. Is it a recursive set or only a recursively enumerable set?

The development is with the curry enumeration peer.

Theorem (`example_716`). Currying between function spaces is computable, and its neighbourhood relation is decidable from the presentations.

Proof. By the curry enumeration. ■

4.8.42 List recursion

Pairing, projection, and the recursion map on the list domain are computable.

Definition (`DsharpRecursion.GRel`). The recursion relation is generated by three clauses: the list-domain master relates to the codomain master; an embedded leaf relates through the map u; and an embedded pair relates through recursively related children followed by the binary map v.

Theorem (`DsharpRecursion.embZero_ne_embPair_of_memS`). An embedded leaf cannot equal an embedded pair whose left component is a list-domain neighbourhood.

Proof. The pair has an element with a nonempty path, whereas every element of an embedded leaf has the empty path. ■

Theorem (`DsharpRecursion.gRel_cod`). Every codomain set occurring in the recursion relation is a codomain neighbourhood.

Proof. Induct over the three constructors and use codomain preservation of u and v. ■

Theorem (`DsharpRecursion.gRel_dom`). Every domain set occurring in the recursion relation is a list-domain neighbourhood.

Proof. Induct over the constructors, using the master, leaf, and pair clauses for list-domain neighbourhoods. ■

Theorem (`DsharpRecursion.gRel_embPair_inv`). A recursion derivation from an embedded pair decomposes into derivations from both children and one application of v.

Proof. Master and leaf derivations are excluded by the distinct shapes; injectivity of pair embedding identifies the two children in the remaining case. ■

Theorem (`DsharpRecursion.gRel_embZero_inv`). A recursion derivation from an embedded leaf is exactly a relation of that leaf neighbourhood through u.

Proof. The master and pair shapes are impossible, leaving the leaf constructor. ■

Theorem (`DsharpRecursion.gRel_gamma_inv`). A recursion derivation from the list-domain master has the codomain master as its target.

Proof. Leaf and pair shapes are distinct from the master, so only the master constructor is possible. ■

Theorem (`DsharpRecursion.gRel_interRight`). For a fixed domain neighbourhood, the recursion relation is closed under intersection of targets.

Proof. Induct over the first derivation, invert the second by shape, intersect corresponding child targets, and use intersection closure of u or v. ■

Theorem (`DsharpRecursion.gRel_master`). Every list-domain neighbourhood is related to the codomain master.

Proof. Induct over its master, leaf, and pair construction, using the master relations of u and v. ■

Theorem (`DsharpRecursion.gRel_mono`). The recursion relation is downward monotone in its domain neighbourhood and upward monotone in its codomain neighbourhood.

Proof. Induct over a derivation, decompose smaller leaves or pairs by shape, and apply monotonicity of u and v. ■

Definition (`DsharpRecursion.gMap`). The recursion relation, with its domain, codomain, master, intersection, and monotonicity properties, defines an approximable map from the list domain to the codomain.

Theorem (`DsharpRecursion.gMap_rel`). The relation of the recursion map is the inductively generated recursion relation.

Proof. This is the defining relation. ■

Definition (`DsharpRecursion.gStep`). One coded evaluation step inspects the node shape and certificate: it checks master equality at a master node, a witness for u at a leaf, or two previously tabulated child certificates and a witness for v at a pair node.

Definition (`DsharpRecursion.gEval`). Coded recursion evaluation is course-of-values recursion generated by one evaluation step.

Theorem (`DsharpRecursion.gEval_pair`). Evaluation at a coded node and certificate is one step applied to that input together with its table of preceding evaluations.

Proof. This is the defining equation of course-of-values recursion. ■

Theorem (`DsharpRecursion.gMap_in`). Applying the recursion map after the list-domain leaf injection agrees with applying u.

Proof. Membership on either side decomposes into a leaf neighbourhood and the leaf inversion theorem converts the recursion relation to the relation of u. ■

Theorem (`DsharpRecursion.gMap_pair`). Applying the recursion map to a paired pair of list-domain elements agrees with applying v to the pair of their recursive images.

Proof. Decompose pair neighbourhoods and use pair inversion in one direction and the pair constructor in the other. ■

Theorem (`DsharpRecursion.gMap_strict`). The recursion map is strict.

Proof. Any relation from the list-domain master has codomain master by master inversion. ■

Theorem (`DsharpRecursion.gStep_gamma`). At a master-shaped node, one evaluation step returns the master-equality test and the proposed output index.

Proof. The master branch is selected by the node code. ■

Theorem (`DsharpRecursion.gStep_leaf`). At a leaf-shaped node, one evaluation step returns the u-witness test and the proposed output index.

Proof. The odd-node branch is selected and its leaf index is recovered by halving. ■

Theorem (`DsharpRecursion.gStep_node`). At a pair-shaped node, one evaluation step multiplies the success bits of both tabulated children with the v-witness test, and returns the proposed output index.

Proof. The positive even-node branch is selected and its two child addresses are decoded. ■

Theorem (`DsharpRecursion.gEval_out`). Evaluation preserves the proposed output index stored in the certificate.

Proof. Split into master, leaf, and pair node shapes; every step equation has that same second component. ■

Theorem (`DsharpRecursion.listGet_rtbl_gEval`). Looking up an earlier address in the evaluation table returns the evaluation at that address.

Proof. This is the defining property of the course-of-values table. ■

Theorem (`DsharpRecursion.pair_le_pair_right`). Pair coding is monotone in its second argument.

Proof. Compare the two branches of the pairing formula and use monotonicity of squaring. ■

Theorem (`DsharpRecursion.pair_lt_pair_left`). Pair coding is strictly monotone in its first argument.

Proof. A case analysis on which coordinate dominates in the pairing formula gives the strict inequality. ■

Theorem (`DsharpRecursion.pair_lt_pair_of_lt_le`). If the first coordinate strictly increases and the second weakly increases, the paired code strictly increases.

Proof. Combine strict monotonicity in the first coordinate with monotonicity in the second. ■

Theorem (`DsharpRecursion.gEval_complete`). Every recursion derivation from a numbered list-domain neighbourhood has a certificate whose evaluation succeeds and whose output index names the target neighbourhood.

Proof. Use strong induction on the node code. Master and leaf derivations supply direct witnesses; a pair derivation combines certificates for its smaller children with a witness for v. ■

Theorem (`DsharpRecursion.primrec_gStep`). If the three certificate tests are primitive recursive, then one coded evaluation step is primitive recursive.

Proof. Every decoded field, table lookup, arithmetic test, branch selection, and call to a certificate test is primitive recursive. ■

Theorem (`DsharpRecursion.unpair_snd_snd_fst_le`). The first component reached after two second projections of a code is at most the original code.

Proof. Each pairing projection is bounded by its source. ■

Theorem (`DsharpRecursion.unpair_snd_snd_snd_le`). The component reached after three second projections of a code is at most the original code.

Proof. Compose the bounds for successive second projections. ■

Theorem (`DsharpRecursion.gEval_sound`). Every successful evaluation certificate yields a derivation in the recursion relation for the named output neighbourhood.

Proof. Use strong induction on the paired node-and-certificate address. Master and leaf successes invoke their relation tests; pair success supplies successful smaller child evaluations and a witness for v. ■

Theorem (`DsharpRecursion.gMap_isComputable`). If u and v are computable, then their list-domain recursion map is computable.

Proof. Extract primitive-recursive witness tests for u, v, and equality with the master. Soundness and completeness identify the recursion relation with existence of a successful evaluation certificate, making it recursively enumerable. ■

4.8.43 Exercise 7.17 — recursion over lists

Complete the proof of 7.7 for showing that $D^{\S}$ is effectively given if D is. Include all the combinators of 6.2. Prove also that if E is effectively given and $u : D \to E$ and $v : E \times E \to E$ are computable, then the unique strict mapping $g : D^{\S} \to E$, where, for $x \in |D|$ and $y, z \in |E|$,

$$g(\mathrm{in}(x)) = u(x), \quad \text{and}$$

$$g(\mathrm{pair}(y, z)) = v(g(y), g(z)),$$

is a computable mapping.

The development is with the list recursion peer.

Theorem (`example_717`). Pairing and the second projection on the list domain are computable.

Proof. By the list-domain combinators. ■

Theorem (`example_717_part2`). The recursion map determined by a computable step on the list domain is computable.

Proof. By evaluation of the recursion along a finite chain. ■

4.8.44 Effective isomorphism

An effective isomorphism is a computable pair of inverse approximable maps, and an iterate is effectively isomorphic to its iterate.

Definition (`EffectiveIso`). An effective isomorphism between two presented systems consists of computable approximable maps in both directions whose two composites are the corresponding identity maps.

Definition (`EffectivelyIsomorphic`). Two computably presented systems are effectively isomorphic when an effective isomorphism between them exists.

Definition (`EffectiveIso.fiber2`). The (i, j)-fibre of a doubly indexed set is the j-th fibre of its i-th fibre.

Theorem (`EffectiveIso.mem_fiber2`). An element belongs to the (i, j)-fibre exactly when the doubly paired element belongs to the original set.

Proof. This is the defining membership condition for two successive fibres. ■

Theorem (`EffectiveIso.fiber2_inter`). Taking a double fibre preserves intersections.

Proof. Fibre membership is pointwise membership, which preserves conjunction. ■

Theorem (`EffectiveIso.fiber2_master`). Every double fibre of the master of a double iterate is the original master.

Proof. Each of the two successive master fibres is a master. ■

Theorem (`EffectiveIso.fiber2_mono`). Inclusion of doubly indexed sets induces inclusion of every double fibre.

Proof. Apply the original inclusion to the paired element. ■

Theorem (`EffectiveIso.mem_fiber2_of_mem`). Every double fibre of a double-iterate neighbourhood is an original neighbourhood.

Proof. The outer fibre is an iterate neighbourhood and its inner fibre is therefore an original neighbourhood. ■

Definition (`EffectiveIso.reindexF`). Forward reindexing replaces a single coordinate coded by a pair with two successive coordinates.

Theorem (`EffectiveIso.fiber2_reindexF`). The (i, j)-fibre after forward reindexing is the original fibre at the paired index (i, j).

Proof. This is immediate from the membership definition. ■

Definition (`EffectiveIso.reindexG`). Backward reindexing replaces two successive coordinates with the two components decoded from one coordinate.

Theorem (`EffectiveIso.fiber_reindexG`). The fibre at k after backward reindexing is the original double fibre at the two components of k.

Proof. This is immediate from the membership definition. ■

Theorem (`EffectiveIso.exists_inner_bound`). For every double-iterate neighbourhood and every finite number of outer fibres, there is one bound beyond which all their inner fibres are master.

Proof. Induct over the number of outer fibres and take the maximum of the previous bound and the new fibre's bound. ■

Theorem (`EffectiveIso.pair_lt_pair_of_lt`). If both coordinates strictly increase, their paired code strictly increases.

Proof. Bound the first pair below the square following its largest coordinate and the second pair above the square of its largest coordinate. ■

Theorem (`EffectiveIso.reindexF_mem`). Forward reindexing sends iterate neighbourhoods to double-iterate neighbourhoods.

Proof. All double fibres are original neighbourhoods, inner fibres become master beyond the original bound, and outer fibres do likewise. ■

Theorem (`EffectiveIso.reindexF_subset_iff`). Forward reindexing of W is included in S exactly when every fibre of W at (i, j) is included in the (i, j)-fibre of S.

Proof. Set inclusion is equivalent to inclusion of all successive fibres. ■

Definition (`EffectiveIso.Fmap`). The forward approximable map relates W to S when both are neighbourhoods and every paired fibre of W is included in the corresponding double fibre of S.

Theorem (`EffectiveIso.Fmap_rel`). The relation of the forward map is exactly its neighbourhood and fibrewise inclusion conditions.

Proof. This is its defining relation. ■

Theorem (`EffectiveIso.reindexG_mem`). Backward reindexing sends double-iterate neighbourhoods to iterate neighbourhoods.

Proof. Use a common inner bound for the finitely many nonmaster outer fibres; any paired index beyond the paired bounds has either a master outer fibre or a master inner fibre. ■

Theorem (`EffectiveIso.reindexG_subset_iff`). Backward reindexing of S is included in W exactly when each decoded double fibre of S is included in the corresponding fibre of W.

Proof. Inclusion is equivalent to inclusion of every single fibre. ■

Definition (`EffectiveIso.Gmap`). The backward approximable map relates S to W when both are neighbourhoods and every decoded double fibre of S is included in the corresponding fibre of W.

Theorem (`EffectiveIso.Gmap_rel`). The relation of the backward map is exactly its neighbourhood and fibrewise inclusion conditions.

Proof. This is its defining relation. ■

Theorem (`EffectiveIso.Fmap_comp_Gmap`). Forward reindexing after backward reindexing is the identity approximable map on the double iterate.

Proof. A mediating reindexed neighbourhood converts the two fibrewise inclusions into ordinary inclusion, and backward reindexing itself supplies a mediator for the converse. ■

Theorem (`EffectiveIso.Gmap_comp_Fmap`). Backward reindexing after forward reindexing is the identity approximable map on the iterate.

Proof. Pairing and unpairing identify the intermediate fibres, reducing the composite relation to inclusion. ■

Theorem (`EffectiveIso.fiber2_iterEnum_iter`). The (i, j)-fibre of a doubly iterated enumerated neighbourhood is the original neighbourhood indexed first by its outer code at i, then by that inner code at j.

Proof. Apply the fibre equation for the iterate enumeration twice. ■

Theorem (`EffectiveIso.Gmap_rel_enum_iff`). On enumerated neighbourhoods, the backward-map relation is equivalent to finitely many inclusions from decoded double fibres into target fibres below the target code.

Proof. The general fibrewise relation gives these inclusions; beyond the target bound the target fibre is master, so no further test is needed. ■

Theorem (`EffectiveIso.Gmap_isComputable`). The backward reindexing map is computable for the iterate presentations.

Proof. The finite characterization uses primitive-recursive nested index lookup and decidable inclusion, followed by bounded universal quantification. ■

Theorem (`EffectiveIso.masterIdx_iterPresentation`). The master index of an iterate presentation is zero.

Proof. This is the chosen master code in the construction. ■

Theorem (`EffectiveIso.Fmap_rel_enum_iff`). On enumerated neighbourhoods, the forward-map relation is equivalent to the finitely bounded family of inclusions from paired source fibres into nested target fibres.

Proof. The general fibrewise relation gives the bounded conditions; outside the outer or inner code bounds the target fibre is master. ■

Theorem (`EffectiveIso.Fmap_isComputable`). The forward reindexing map is computable for the iterate presentations.

Proof. Its finite characterization consists of primitive-recursive nested lookups, decidable inclusion, and two bounded universal quantifiers. ■

Definition (`EffectiveIso.iterIterEffectiveIso`). The forward and backward reindexing maps, with their computability and inverse laws, form an effective isomorphism between an iterate and its double iterate.

Definition (`EffectiveIso.toDomainIso`). An effective isomorphism induces an order isomorphism of element domains by applying its two approximable maps to elements.

Theorem (`EffectivelyIsomorphic.isomorphic`). Effectively isomorphic presentations have isomorphic element domains.

Proof. Choose an effective isomorphism and pass to its induced domain isomorphism. ■

Theorem (`iterSys_effectivelyIsomorphic_iterIter`). Every presented iterate is effectively isomorphic to its double iterate.

Proof. Use the effective isomorphism supplied by forward and backward reindexing. ■

Theorem (`iterSys_isomorphic_iterIter`). An iterate neighbourhood system is isomorphic to its double iterate.

Proof. Forget the computability data from the effective reindexing isomorphism. ■

4.8.45 Exercise 7.18 — effective isomorphism

Two effectively given systems D and E are *effectively isomorphic* iff … (complete the sentence!). Show that if D is effectively given then the isomorphism

$$D^\infty \cong (D^\infty)^\infty$$

is effective.

The development is with the effective isomorphism peer.

Theorem (`example_718`). An iterate is effectively isomorphic to the iterate of that iterate.

Proof. By the effective isomorphism. ■

4.8.46 Powerdomain functor

The powerdomain construction sends an approximable map to an approximable map, preserving identity and composition, and the result is computable.

Definition (`PFmap`). For an approximable map from one neighbourhood system to another, define its powerdomain action by relating two finite upper families when every source neighbourhood has a related target neighbourhood in the target family.

Theorem (`PFmap_rel`). Two powerdomain neighbourhoods are related by the lifted map exactly when they are valid powerdomain neighbourhoods and every member of the first has a related member of the second.

Proof. This is exactly the relation used to define the powerdomain action. ■

Definition (`PFmapComb`). Define the higher-order powerdomain operator that sends each neighbourhood of approximable maps to a neighbourhood containing every corresponding lifted map.

Theorem (`PFmapComb_rel`). A function-space neighbourhood and a lifted function-space neighbourhood are related exactly when every map in the former has its powerdomain lifting in the latter.

Proof. The equivalence is the defining condition of the higher-order relation. ■

Theorem (`PDmem_mem`). Every member of a powerdomain neighbourhood is itself a neighbourhood of the underlying system.

Proof. A powerdomain neighbourhood is a finite union of principal upper families generated by neighbourhoods. Membership therefore supplies a generator contained in the given member, and upward closure makes that member a neighbourhood. ■

Theorem (`PFmap_idMap`). Lifting the identity approximable map to powerdomains gives the identity map on the powerdomain.

Proof. If every source member is related by the identity to a target member, then each source member lies in the target family by downward closure. Conversely, inclusion of the source family in the target family

lets each member witness itself. ■

Theorem (`PFmap_rel_Ypd_iff`). For presented powerdomain neighbourhoods, the lifted relation holds exactly when every decoded source index has a decoded target index whose basic neighbourhoods are related.

Proof. In the forward direction, apply the lifted relation to each basic source neighbourhood and choose a basic target neighbourhood below the resulting member. In the reverse direction, choose basic generators below arbitrary family members and use monotonicity of the original map. ■

Theorem (`PFmap_rel_fin`). For finite upper families generated by two lists, the lifted relation holds exactly when every generator in the source list has a related generator in the target list.

Proof. Applying the lifted relation to a source generator yields a target-family member, hence a target generator below it; codomain monotonicity gives the required generator relation. Conversely, choose the stipulated target generator below each arbitrary source-family member and use domain monotonicity. ■

Theorem (`bExists_decodeList_re`). If a binary relation is recursively enumerable, then the relation saying that some member of a decoded finite list is related to a given number is recursively enumerable.

Proof. Membership in a decoded finite list is decidable. Conjoining it with the given enumerable relation and projecting away the candidate witness preserves recursive enumerability. ■

Theorem (`PFmap_isComputable_Ypd`). On the canonical enumerations of powerdomain neighbourhoods, the relation induced by the lifted map is recursively enumerable.

Proof. The finite-code characterization reduces the relation to a bounded universal quantifier over source indices followed by a bounded existential quantifier over target indices. Recursive enumerability is preserved by both finite quantifiers and by exchanging the paired inputs. ■

Theorem (`PFmap_isComputable`). The powerdomain lifting of a computable approximable map is computable for the induced computable powerdomain presentations.

Proof. Computability for these presentations is precisely recursive enumerability on their canonical coded neighbourhoods, supplied by the preceding theorem. ■

Theorem (`comp_witness`). Given finitely many source neighbourhoods whose composites reach a target family, one can choose a finite intermediate family witnessing both stages of the composite.

Proof. Induct on the source list. The empty list uses no intermediates. For a new head, choose one of its intermediate witnesses, prepend it to the list obtained for the tail, and retain the corresponding witnesses for both stages. ■

Theorem (`PFmap_comp`). Powerdomain lifting preserves composition of approximable maps.

Proof. For the forward implication, express the source family by finitely many generators and collect finitely many intermediate witnesses; their generated upper family witnesses the composite of the two lifted maps. For the reverse implication, compose the two witnesses chosen successively for each source member. ■

Theorem (`gather_witnesses`). Finite pointwise existential witnesses can be collected into a finite list of related source–target pairs, with at least one pair for each source.

Proof. Induct on the source list, choosing one target witness for the head and adjoining that pair to the collection furnished for the tail. ■

Theorem (`exists_stepFun_forall_PFmap_rel`). Any finite family of lifted constraints satisfied by a map is forced by finitely many ordinary step constraints satisfied by that map.

Proof. For one lifted constraint, write its two powerdomain neighbourhoods using finite generators and collect one related pair for each source generator. For a finite list of constraints, append these pairs to the pairs obtained inductively; any map satisfying all collected pairs satisfies each lifted constraint by the finite-generator characterization. ■

Theorem (`PFmapComb_toElementMap`). On elements, the higher-order lifting operator sends the filter of a map to the filter of its powerdomain lifting.

Proof. One inclusion applies the defining universal condition to the given map. For the other, each finite neighbourhood of the lifted map is forced by finitely many step constraints; the function-space neighbourhood generated by those constraints contains the original map and is sent inside the chosen lifted neighbourhood. ■

4.8.47 Exercise 7.19 — power domain functor

Prove that $D \mapsto \mathbb{P}D$ is a functor by defining for each $f : D \to E$ a mapping

$$\mathbb{P}f : \mathbb{P}D \to \mathbb{P}E$$

by the formula

$$\bigcup_{i<n} \downarrow X_i \quad \mathbb{P}f \quad \bigcup_{j<m} \downarrow Y_j \quad \text{iff} \quad \forall i < n \exists j < m.\, X_i f Y_j\,.$$

Be sure to check that $\mathbb{P}f$ is approximable and that $\mathbb{P}$ preserves identity maps and composition. If f is computable, is $\mathbb{P}f$? Is there a combinator $\lambda f.\, \mathbb{P}f$? What is

$$\mathbb{P}f(\{x, y\}) = ??$$

The development is with the powerdomain functor peer.

Theorem (`example_719`). The direct-image map on powerdomains preserves composition and identities and is computable.

Proof. By the powerdomain functor. ■

4.8.48 Powerdomain union

Union of neighbourhoods is a computable map on the powerdomain.

Definition (`unionMap`). Define union on the iterated powerdomain by relating a family of families to a target family when every neighbourhood occurring in a source member is contained in some target member.

Theorem (`unionMap_rel`). The union relation holds exactly when its arguments are valid powerdomain neighbourhoods and every neighbourhood occurring in the source is contained in a member of the target.

Proof. This equivalence is the relation by which union on the iterated powerdomain is defined. ■

Theorem (`unionMap_rel_Ypd_iff`). For canonical presented neighbourhoods, union holds exactly when every doubly decoded source index is contained in a basic neighbourhood indexed by the decoded target list.

Proof. Given the union relation, apply it to canonical basic members selected by the two source indices, then choose a basic target generator below the resulting member. Conversely, represent arbitrary source members by decoded basic generators and compose their inclusions with the assumed inclusion into a decoded target generator. ■

Theorem (`ypd_zero_subset_inter`). The zeroth presented powerdomain neighbourhood, which is empty, is contained in the intersection of any two presented powerdomain neighbourhoods.

Proof. The zeroth code decodes to the empty family, which is contained in every set and hence in the stated intersection. ■

Theorem (`unionMap_isComputable`). Union from the iterated powerdomain to the powerdomain is computable for the canonical powerdomain presentations.

Proof. By the canonical-code characterization, the union relation is a finite succession of universal list quantifiers followed by existence of a target index satisfying decidable basic inclusion. This predicate is decidable, and therefore recursively enumerable. ■

Theorem (`unionMap_rel_fin`). For finitely generated upper families, union holds exactly when every generator in every source list is contained in a target generator.

Proof. Forward, apply union to each source generator and then choose a target generator below the resulting target member. Reverse, choose generators below an arbitrary source family and one of its members; the assumed generator inclusion, followed by these two containments, supplies the required target witness. ■

4.8.49 Exercise 7.20 — union on power domains

Show that there is a combinator

$$\text{union} : \mathbb{P}(\mathbb{P}D) \to \mathbb{P}D$$

where for suitable neighbourhoods

$$\bigcup_{i<n} \downarrow \left(\bigcup_{j<m_i} \downarrow X_{ij} \right) \quad \text{union} \quad \bigcup_{k<q} \downarrow Y_k \quad \text{iff} \quad \forall i < n \forall j < m_i \exists k < q.\, X_{ij} \subseteq Y_k\,.$$

Is union computable if D is effectively given? What is

$$\text{union}(\{\{x\}, \{y, z\}\}) = ??$$

Are $\mathbb{P}(\mathbb{P}D)$ and $\mathbb{P}D$ generally isomorphic??

The development is with the powerdomain union peer.

Theorem (`example_720`). Union is a computable map on the powerdomain.

Proof. By the powerdomain union. ■

4.8.50 Pointwise application

Evaluation distributes over the powerdomain of a function space.

Definition (`papplyEval`). Define powerdomain evaluation by requiring every function neighbourhood in the first family and every argument neighbourhood in the second to evaluate into some member of the result family.

Theorem (`papplyEval_rel`). Powerdomain evaluation relates three families exactly when they are valid powerdomain neighbourhoods and every function–argument pair has an evaluation witness in the result family.

Proof. This is precisely the relation defining powerdomain evaluation. ■

Definition (`papplyB`). Define uncurried powerdomain application by viewing powerdomain evaluation as a map out of the product of function and argument powerdomains.

Definition (`papply`). Define powerdomain application as the currying of uncurried powerdomain evaluation.

Theorem (`papplyEval_rel_Ypd_iff`). On canonical presentations, powerdomain evaluation holds exactly when every decoded function index and decoded argument index have a decoded result index witnessing ordinary evaluation.

Proof. Forward, apply powerdomain evaluation to the basic function and argument neighbourhoods selected by the decoded indices, then choose a basic result neighbourhood below the witness. Reverse, choose decoded basic neighbourhoods below arbitrary function and argument members and enlarge the resulting basic evaluation witness by monotonicity. ■

Theorem (`papplyEval_step_witness`). A principal family generated by a single step function evaluates its principal argument family into the corresponding principal result family.

Proof. Every function in the principal family contains the generating step, and every argument in the principal argument family contains its input neighbourhood. The step relation therefore sends that argument to the generating result neighbourhood, which itself belongs to the principal result family. ■

Theorem (`re_forallG_forallX_existsY`). Recursive enumerability is preserved by bounded universal quantification over two decoded finite lists followed by bounded existential quantification over a third.

Proof. First combine the enumerable relation with decidable membership in the result list and project out the result witness. Then apply bounded universal quantification over the argument list and over the function list, rearranging the nested pair coding between these stages. ■

Theorem (`papplyEval_isComputable`). If ordinary evaluation on the chosen presentations is recursively enumerable, then powerdomain evaluation on their canonical finite-family presentations is recursively enumerable.

Proof. The canonical-code characterization identifies powerdomain evaluation with two bounded universal quantifiers and one bounded existential quantifier applied to ordinary evaluation. The preceding closure theorem therefore makes this coded relation recursively enumerable. ■

4.8.51 Exercise 7.21 — distributing the power domain

Is there a non-trivial combinator of type

$$\mathbb{P}(D \to E) \to (\mathbb{P}D \to \mathbb{P}E)\,?$$

Are there in general any isomorphisms between the systems

$$(D \to \mathbb{P}E),\ \mathbb{P}(D \times E),\ \mathbb{P}D \times \mathbb{P}E\ ??$$

Is there a non-trivial combinator of type

$$\mathbb{P}(D \times E) \times \mathbb{P}(E \times F) \to \mathbb{P}(D \times F)\ ???$$

Is there any connection between

$$\mathbb{P}\mathbf{N} \text{ and } P\mathbf{N}\ ????$$

The development is with the pointwise application peer.

Theorem (`example_721`). Pointwise application on the powerdomain of a function space is computable, and it holds of enumerated neighbourhoods exactly when every pair from the first two lists meets the relation in some element of the third.

Proof. By pointwise application. ■

4.8.52 Regular languages

Expressions, automata, and the neighbourhood system of formal languages.

Definition (`concat`). The concatenation of two languages consists of all words obtained by appending a word of the second language to a word of the first.

Definition (`InS`). The admissible regular languages are generated by the universal language and singleton languages, and are closed under concatenation and nonempty intersection.

Theorem (`mem_concat`). The element described by concat belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for concat is supplied directly by the defining membership condition. ■

Theorem (`Ssys_master_mem`). The master neighbourhood in ssys master mem is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for ssys master mem and applying the preceding component lemmas yields the claimed result. ■

Theorem (`Ssys_master_nonempty`). The set or language ssys master nonempty has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in ssys master nonempty and combine them using the defining construction. ■

Theorem (`Ssys_sub_master`). The master neighbourhood in ssys sub master is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for ssys sub master and applying the preceding component lemmas yields the claimed result. ■

Theorem (`concat_mono`). Enlarging the input sets in concat mono can only enlarge its resulting set or element.

Proof. Transport every witness for concat mono along the assumed inclusions; the same witness then belongs to the enlarged result. ■

Theorem (`concat_nonempty`). The set or language concat nonempty has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in concat nonempty and combine them using the defining construction. ■

Theorem (`InS.nonempty`). The set or language nonempty has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in nonempty and combine them using the defining construction. ■

Theorem (`Ssys_inter_mem`). The construction ssys inter mem preserves the specified intersection of sets or neighbourhoods.

Proof. Use the same witnesses in both directions for ssys inter mem, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Definition (`Ssys`). The regular-language neighbourhood system has all Boolean words as master set and the nonempty languages generated from the universal language and singleton languages by concatenation and intersection as neighbourhoods.

Theorem (`Ssys_mem`). For the objects in ssys mem, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for ssys mem and applying the preceding component lemmas yields the claimed result. ■

Definition (`mulElem`). Multiplication of language elements is induced by concatenating every neighbourhood from the first element with every neighbourhood from the second.

Theorem (`mem_mulElem`). The element described by mul elem belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for mul elem is supplied directly by the defining membership condition. ■

Definition (`emb`). A word is embedded as the principal language element generated by its singleton language.

Theorem (`mem_emb`). The element described by emb belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for emb is supplied directly by the defining membership condition. ■

Definition (`prependMap`). Prefixing by a fixed word defines an approximable endomap of the regular-language neighbourhood system.

Definition (`repeatWord`). The nth repetition of a word is obtained by concatenating n copies, with the zeroth repetition equal to the empty word.

Theorem (`repeatWord_zero`). At input zero, repeat word has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of repeat word zero gives this equation immediately. ■

Definition (`powerLang`). The power language of a word is the set of all of its finite repetitions.

Theorem (`mem_powerLang`). The element described by power lang belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for power lang is supplied directly by the defining membership condition. ■

Definition (`streamArrow`). The stream arrow of a word is the least fixed point of prefixing by that word.

Definition (`streamElemMem`). A language neighbourhood belongs to the stream element of a word when it contains a sufficiently long finite power of that word.

Definition (`streamElem`). The stream element generated by a word consists of all admissible languages containing some finite power of that word.

Theorem (`append_mem_concat`). For the objects in append mem concat, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for append mem concat and applying the preceding component lemmas yields the claimed result. ■

Theorem (`concat_assoc`). The binary operation concat assoc is associative.

Proof. Reassociate the three word concatenations in witnesses for concat assoc; this converts membership on either side into membership on the other. ■

Theorem (`mulElem_assoc`). The binary operation mul elem assoc is associative.

Proof. Reassociate the three word concatenations in witnesses for mul elem assoc; this converts membership on either side into membership on the other. ■

Theorem (`repeatWord_add`). For the objects in repeat word add, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for repeat word add and applying the preceding component lemmas yields the claimed result. ■

Theorem (`repeatWord_eq_empty`). The set or language in repeat word eq empty is empty exactly under the stated absence-of-witness condition.

Proof. An element of the set in repeat word eq empty would provide exactly the forbidden witness, while any such witness produces an element; hence emptiness is equivalent to its absence. ■

Theorem (`InS_powerLang_empty`). The set or language in in s power lang empty is empty exactly under the stated absence-of-witness condition.

Proof. An element of the set in in s power lang empty would provide exactly the forbidden witness, while any such witness produces an element; hence emptiness is equivalent to its absence. ■

Theorem (`mem_streamElem`). The element described by stream elem belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for stream elem is supplied directly by the defining membership condition. ■

Theorem (`streamElem_powers_of_mul`). The hypotheses mul imply stream elem powers.

Proof. Following the defining recursion for stream elem powers of mul and applying the preceding component lemmas yields the claimed result. ■

Theorem (`streamElem_mul_self_mem`). The element in stream elem mul self mem is idempotent under language multiplication.

Proof. Finite powers are closed under addition of exponents, so neighbourhood membership for stream elem mul self mem is unchanged by multiplying the element by itself. ■

Theorem (`streamElem_idempotent`). The element in stream elem idempotent is idempotent under language multiplication.

Proof. Finite powers are closed under addition of exponents, so neighbourhood membership for stream elem idempotent is unchanged by multiplying the element by itself. ■

Theorem (`Ssys_isPositive`). For the objects in ssys is positive, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for ssys is positive and applying the preceding component lemmas yields the claimed result. ■

Theorem (`Ssys_master`). The master neighbourhood in ssys master is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for ssys master and applying the preceding component lemmas yields the claimed result. ■

Theorem (`concat_singleton`). For the objects in concat singleton, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for concat singleton and applying the preceding component lemmas yields the claimed result. ■

Theorem (`emb_injective`). The construction emb injective sends equal outputs only from equal inputs.

Proof. Equality of two values of emb injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`emb_mul`). For the objects in emb mul, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for emb mul and applying the preceding component lemmas yields the claimed result. ■

Theorem (`mulElem_bot_le`). The element or numerical value mul elem bot le lies below the bound in the theorem.

Proof. Following the defining recursion for mul elem bot le and applying the preceding component lemmas yields the claimed result. ■

Theorem (`mulElem_mono_right`). Enlarging the input sets in mul elem mono right can only enlarge its resulting set or element.

Proof. Transport every witness for mul elem mono right along the assumed inclusions; the same witness then belongs to the enlarged result. ■

Theorem (`powerLang_concat`). For the objects in power lang concat, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for power lang concat and applying the preceding component lemmas yields the claimed result. ■

Theorem (`prependMap_toElementMap`). For the objects in prepend map to element map, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for prepend map to element map and applying the preceding component lemmas yields the claimed result. ■

Theorem (`repeatWord_succ`). At a successor input, repeat word succ satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of repeat word succ gives this equation immediately. ■

Theorem (`streamArrow_eq`). The value of stream arrow eq equals the value described by stream arrow eq.

Proof. Compare membership or numerical components in stream arrow eq; the defining equations reduce both sides to the same data. ■

Theorem (`prependMap_iterElem_mul_streamArrow_le`). The element or numerical value prepend map iter elem mul stream arrow le lies below the bound in the theorem.

Proof. Following the defining recursion for prepend map iter elem mul stream arrow le and applying the preceding component lemmas yields the claimed result. ■

Theorem (`streamArrow_le_mul_self`). The element in stream arrow le mul self is idempotent under language multiplication.

Proof. Finite powers are closed under addition of exponents, so neighbourhood membership for stream arrow le mul self is unchanged by multiplying the element by itself. ■

Theorem (`streamArrow_mul_self_le`). The element in stream arrow mul self le is idempotent under language multiplication.

Proof. Finite powers are closed under addition of exponents, so neighbourhood membership for stream arrow mul self le is unchanged by multiplying the element by itself. ■

Theorem (`streamArrow_mul_self`). The element in stream arrow mul self is idempotent under language multiplication.

Proof. Finite powers are closed under addition of exponents, so neighbourhood membership for stream arrow mul self is unchanged by multiplying the element by itself. ■

Theorem (`streamArrow_containsZero_pow_four`). For the objects in stream arrow contains zero pow four, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for stream arrow contains zero pow four and applying the preceding component lemmas yields the claimed result. ■

Theorem (`streamArrow_mul_self_append_true`). The element in stream arrow mul self append true is idempotent under language multiplication.

Proof. Finite powers are closed under addition of exponents, so neighbourhood membership for stream arrow mul self append true is unchanged by multiplying the element by itself. ■

Theorem (`streamArrow_mul_self_self`). The element in stream arrow mul self self is idempotent under language multiplication.

Proof. Finite powers are closed under addition of exponents, so neighbourhood membership for stream arrow mul self self is unchanged by multiplying the element by itself. ■

Definition (`SExpr`). A regular-language expression is either the universal language, a singleton word, a concatenation, or an intersection.

Definition (`sexprOfNatFuel`). The fuel-bounded expression decoder reads a natural-number pairing code and recursively reconstructs a regular-language expression while fuel remains.

Definition (`sexprOfNat`). A natural number is decoded as an expression using one more unit of fuel than its own value.

Definition (`sexprToNat`). Expressions are encoded by assigning constructor tags and pairing the recursively encoded subexpressions.

Theorem (`snd_lt_pair_of_pos_fst`). The hypotheses pos fst imply snd lt pair.

Proof. Following the defining recursion for snd lt pair of pos fst and applying the preceding component lemmas yields the claimed result. ■

Theorem (`sexprOfNatFuel_sexprToNat`). For the objects in sexpr of nat fuel sexpr to nat, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for sexpr of nat fuel sexpr to nat and applying the preceding component lemmas yields the claimed result. ■

Definition (`denote`). The denotation of an expression interprets the four constructors as the universal language, singleton, concatenation, and intersection.

Theorem (`denote_sigma`). For the objects in denote sigma, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for denote sigma and applying the preceding component lemmas yields the claimed result. ■

Theorem (`denote_single`). For the objects in denote single, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for denote single and applying the preceding component lemmas yields the claimed result. ■

Theorem (`denote_cat`). For the objects in denote cat, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for denote cat and applying the preceding component lemmas yields the claimed result. ■

Theorem (`denote_cap`). For the objects in denote cap, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for denote cap and applying the preceding component lemmas yields the claimed result. ■

Definition (`matchesB`). The Boolean matcher decides whether a finite Boolean word belongs to the language denoted by an expression.

Theorem (`mem_concat_iff_split`). Membership in concat iff split is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of concat iff split exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`matchesB_iff`). The condition matches b holds exactly when the finite witness condition holds.

Proof. Expand both conditions in matches b iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Definition (`emptyExpr`). The empty-language expression is the intersection of the singleton languages containing false and true.

Theorem (`denote_emptyExpr`). The set or language in denote empty expr is empty exactly under the stated absence-of-witness condition.

Proof. An element of the set in denote empty expr would provide exactly the forbidden witness, while any such witness produces an element; hence emptiness is equivalent to its absence. ■

Definition (`containsZero`). The expression for words containing false is the concatenation of the universal language, the false singleton, and the universal language.

Theorem (`InS_denote_of_nonempty`). The set or language in s denote of nonempty has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in in s denote of nonempty and combine them using the defining construction. ■

Theorem (`InS_exists_denote`). For the objects in in s exists denote, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for in s exists denote and applying the preceding component lemmas yields the claimed result. ■

Theorem (`denote_catSigmaSigma`). For the objects in denote cat sigma sigma, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for denote cat sigma sigma and applying the preceding component lemmas yields the claimed result. ■

Theorem (`empty_iff_equiv_emptyExpr`). The set or language in empty iff equiv empty expr is empty exactly under the stated absence-of-witness condition.

Proof. An element of the set in empty iff equiv empty expr would provide exactly the forbidden witness, while any such witness produces an element; hence emptiness is equivalent to its absence. ■

Theorem (`inS_eq_range_denote`). The value of in s equals the value described by range denote.

Proof. Compare membership or numerical components in in s eq range denote; the defining equations reduce both sides to the same data. ■

Theorem (`inS_iff_exists_denote`). The condition in s holds exactly when exists denote holds.

Proof. Expand both conditions in in s iff exists denote; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`interEq_iff`). The intersection in inter eq iff equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for inter eq iff, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`mem_denote_sigma`). The element described by denote sigma belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for denote sigma is supplied directly by the defining membership condition. ■

Theorem (`sigma_ne_containsZero`). At input zero, sigma ne contains has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of sigma ne contains zero gives this equation immediately. ■

Theorem (`example_722_regular`). Scott's example example 722 regular has the claimed language-theoretic or computability property.

Proof. Following the defining recursion for example 722 regular and applying the preceding component lemmas yields the claimed result. ■

Definition (`catEps`). Concatenation of two nondeterministic automata is represented by an epsilon automaton whose accepting states of the first component have epsilon transitions to the start states of the second.

Theorem (`catEps_step_inl_some`). For the objects in cat eps step inl some, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for cat eps step inl some and applying the preceding component lemmas yields the claimed result. ■

Theorem (`catEps_step_inl_none`). At input one, cat eps step inl has the value specified by its definition.

Proof. Following the defining recursion for cat eps step inl none and applying the preceding component lemmas yields the claimed result. ■

Theorem (`catEps_step_inr_some`). For the objects in cat eps step inr some, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for cat eps step inr some and applying the preceding component lemmas yields the claimed result. ■

Theorem (`catEps_step_inr_none`). At input one, cat eps step inr has the value specified by its definition.

Proof. Following the defining recursion for cat eps step inr none and applying the preceding component lemmas yields the claimed result. ■

Theorem (`catEps_start`). For the objects in cat eps start, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for cat eps start and applying the preceding component lemmas yields the claimed result. ■

Theorem (`catEps_accept`). For the objects in cat eps accept, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for cat eps accept and applying the preceding component lemmas yields the claimed result. ■

Theorem (`catEps_mem_`). For the objects in cat eps mem, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for cat eps mem and applying the preceding component lemmas yields the claimed result. ■

Theorem (`catEps_mem_eval_iff`). Membership in cat eps mem eval iff is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of cat eps mem eval iff exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`catEps_accepts`). The automaton in cat eps accepts accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for cat eps accepts; the accepting-state condition then gives the stated language. ■

Theorem (`example_722_cat`). Scott's example example 722 cat has the claimed language-theoretic or computability property.

Proof. Following the defining recursion for example 722 cat and applying the preceding component lemmas yields the claimed result. ■

Definition (`sigmaDFA`). The automaton sigma dfa has the recursively specified state space, transitions, initial states, and accepting states.

Theorem (`sigmaDFA_accepts`). The automaton in sigma dfa accepts accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for sigma dfa accepts; the accepting-state condition then gives the stated language. ■

Definition (`SingleState`). The state space for recognizing one fixed word consists of its positions together with a failure state.

Definition (`singleDFA`). The automaton single dfa has the recursively specified state space, transitions, initial states, and accepting states.

Theorem (`complDFA_accepts`). The automaton in compl dfa accepts accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for compl dfa accepts; the accepting-state condition then gives the stated language. ■

Theorem (`inter_eval`). Evaluating the automaton or finite transition system in inter eval yields the stated reachable state after reading the word.

Proof. Induction on the input word tracks the reachable states for inter eval; the accepting-state condition then gives the stated language. ■

Theorem (`interDFA_accepts`). The automaton in inter dfa accepts accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for inter dfa accepts; the accepting-state condition then gives the stated language. ■

Theorem (`example_722_dfa`). Scott's example example 722 dfa has the claimed language-theoretic or computability property.

Proof. Following the defining recursion for example 722 dfa and applying the preceding component lemmas yields the claimed result. ■

Theorem (`sigmaDFA_accepts_denote`). The automaton in sigma dfa accepts denote accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for sigma dfa accepts denote; the accepting-state condition then gives the stated language. ■

Theorem (`singleDFA_evalFrom_none`). Evaluating the automaton or finite transition system in single dfa eval from none yields the stated reachable state after reading the word.

Proof. Induction on the input word tracks the reachable states for single dfa eval from none; the accepting-state condition then gives the stated language. ■

Theorem (`singleDFA_evalFrom`). Evaluating the automaton or finite transition system in single dfa eval from yields the stated reachable state after reading the word.

Proof. Induction on the input word tracks the reachable states for single dfa eval from; the accepting-state condition then gives the stated language. ■

Theorem (`singleDFA_accepts`). The automaton in single dfa accepts accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for single dfa accepts; the accepting-state condition then gives the stated language. ■

Theorem (`singleDFA_accepts_denote`). The automaton in single dfa accepts denote accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for single dfa accepts denote; the accepting-state condition then gives the stated language. ■

Definition (`wordsUpTo`). The words of length at most n are enumerated recursively from the empty word by prefixing both Boolean letters.

Definition (`anyMatchesB`). This finite Boolean test reports whether some word of bounded length matches the expression.

Theorem (`mem_wordsUpTo`). The element described by words up to belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for words up to is supplied directly by the defining membership condition. ■

Theorem (`example_722_words`). Scott's example example 722 words has the claimed language-theoretic or computability property.

Proof. Following the defining recursion for example 722 words and applying the preceding component lemmas yields the claimed result. ■

Definition (`pathStateAtAux`). The auxiliary path-state function follows a path up to the requested position, starting from the supplied state.

Definition (`pathStateAt`). The state at a position of a finite automaton path is obtained by the auxiliary path traversal.

Definition (`PathSplit`). A path split records an intermediate state and the two path segments obtained by cutting a path at a chosen position.

Definition (`NFAinter`). The intersection automaton runs two nondeterministic automata in parallel on the product of their state spaces.

Theorem (`NFAinter_mem_eval_iff`). Membership in nfainter mem eval iff is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of nfainter mem eval iff exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`NFAinter_mem_accepts_iff`). Membership in nfainter mem accepts iff is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of nfainter mem accepts iff exposes exactly the witnesses and equations occurring on the other side. ■

Definition (`autState`). The automaton state type associated with an expression is defined recursively from the expression constructors.

Theorem (`dfaToNFA_eval`). Evaluating the automaton or finite transition system in dfa to nfa eval yields the stated reachable state after reading the word.

Proof. Induction on the input word tracks the reachable states for dfa to nfa eval; the accepting-state condition then gives the stated language. ■

Theorem (`dfaToNFA_accepts`). The automaton in dfa to nfa accepts accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for dfa to nfa accepts; the accepting-state condition then gives the stated language. ■

Definition (`autStateCard`). The number of automaton states associated with an expression is computed recursively from its constructors.

Theorem (`pathStateAt_zero`). At input zero, path state at has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of path state at zero gives this equation immediately. ■

Theorem (`accepts_card_zero`). The automaton in accepts card zero accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for accepts card zero; the accepting-state condition then gives the stated language. ■

Theorem (`autStateCard_eq_card`). The value of aut state card equals the value described by card.

Proof. Compare membership or numerical components in aut state card eq card; the defining equations reduce both sides to the same data. ■

Definition (`decideNonemptyB`). Nonemptiness is decided by searching words only up to the finite number of automaton states.

Definition (`decideEmptyB`). Emptiness is the Boolean negation of the nonemptiness decision.

Theorem (`mem_accepts_of_path`). The element described by accepts of path belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for accepts of path is supplied directly by the defining membership condition. ■

Definition (`pathAppend`). Two compatible automaton paths concatenate to a path labelled by the concatenation of their words.

Theorem (`pathStateAt_succ`). At a successor input, path state at succ satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of path state at succ gives this equation immediately. ■

Definition (`pathAppend_take_drop`). Every path is the concatenation of its prefix and suffix obtained by cutting at a bounded position.

Theorem (`accepts_skip_loop`). The automaton in accepts skip loop accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for accepts skip loop; the accepting-state condition then gives the stated language. ■

Theorem (`accepts_shorten_step`). The automaton in accepts shorten step accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for accepts shorten step; the accepting-state condition then gives the stated language. ■

Theorem (`exists_accepted_word_short`). The language in accepted word short is nonempty exactly when it accepts a word shorter than the number of available automaton states.

Proof. Repeatedly remove a loop from any longer accepting path for accepted word short; finiteness of the state set guarantees a repeated state until a short accepted word remains. ■

Definition (`toNFA`). The automaton to nfa has the recursively specified state space, transitions, initial states, and accepting states.

Theorem (`toNFA_accepts`). The automaton in to nfa accepts accepts exactly the words described by the associated language expression.

Proof. Induction on the input word tracks the reachable states for to nfa accepts; the accepting-state condition then gives the stated language. ■

Theorem (`denote_nonempty_iff_short`). The language in denote nonempty iff short is nonempty exactly when it accepts a word shorter than the number of available automaton states.

Proof. Repeatedly remove a loop from any longer accepting path for denote nonempty iff short; finiteness of the state set guarantees a repeated state until a short accepted word remains. ■

Theorem (`decideNonemptyB_iff`). The set or language decide nonempty b iff has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in decide nonempty b iff and combine them using the defining construction. ■

Theorem (`decideEmptyB_iff`). The set or language in decide empty b iff is empty exactly under the stated absence-of-witness condition.

Proof. An element of the set in decide empty b iff would provide exactly the forbidden witness, while any such witness produces an element; hence emptiness is equivalent to its absence. ■

Definition (`consistentB`). Two expressions are consistent when the denotation of their intersection is nonempty.

Theorem (`consistentB_iff`). The condition consistent b holds exactly when the finite witness condition holds.

Proof. Expand both conditions in consistent b iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`capNonempty_iff_consistent`). The set or language cap nonempty iff consistent has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in cap nonempty iff consistent and combine them using the defining construction. ■

Theorem (`autStateCard_le_card`). The element or numerical value aut state card le card lies below the bound in the theorem.

Proof. Following the defining recursion for aut state card le card and applying the preceding component lemmas yields the claimed result. ■

4.8.53 Regular-language codes

Gödel coding and primitive-recursive decision procedures for the regular-language expressions of Exercise 7.22.

Theorem (`consistentB_iff_Ssys`). The condition consistent b holds exactly when ssys holds.

Proof. Expand both conditions in consistent b iff ssys; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`example_722_decide`). Scott's example example 722 decide has the claimed language-theoretic or computability property.

Proof. Following the defining recursion for example 722 decide and applying the preceding component lemmas yields the claimed result. ■

Theorem (`denote_eq_empty_iff`). The set or language in denote eq empty iff is empty exactly under the stated absence-of-witness condition.

Proof. An element of the set in denote eq empty iff would provide exactly the forbidden witness, while any such witness produces an element; hence emptiness is equivalent to its absence. ■

Theorem (`nfa_accepts_nonempty_iff`). The set or language nfa accepts nonempty iff has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in nfa accepts nonempty iff and combine them using the defining construction. ■

Theorem (`nfa_accepts_nonempty_iff_short`). The language in nfa accepts nonempty iff short is nonempty exactly when it accepts a word shorter than the number of available automaton states.

Proof. Repeatedly remove a loop from any longer accepting path for nfa accepts nonempty iff short; finiteness of the state set guarantees a repeated state until a short accepted word remains. ■

Theorem (`pathStateAt_last`). For the objects in path state at last, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for path state at last and applying the preceding component lemmas yields the claimed result. ■

Definition (`acceptFin`). The finite accepting-state set of an expression automaton is computed recursively from the expression.

Definition (`startFin`). The finite initial-state set of an expression automaton is computed recursively from the expression.

Definition (`stepFinSingle`). The state transformer step fin single performs one stage of the finite numerical computation encoded in its state.

Definition (`stepFin`). The state transformer step fin performs one stage of the finite numerical computation encoded in its state.

Definition (`diffNFA`). The automaton diff nfa has the recursively specified state space, transitions, initial states, and accepting states.

Definition (`evalFin`). The finite state set reached after reading a word is obtained by folding the finite transition operation from the finite start set.

Definition (`subsetB`). The set subset b consists exactly of the elements admitted by its defining membership condition.

Definition (`interEqB`). Language equality is tested by checking inclusion in both directions.

Theorem (`coe_acceptFin`). For the objects in accept fin, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for accept fin and applying the preceding component lemmas yields the claimed result. ■

Theorem (`coe_startFin`). For the objects in start fin, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for start fin and applying the preceding component lemmas yields the claimed result. ■

Theorem (`coe_stepFinSingle`). For the objects in step fin single, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for step fin single and applying the preceding component lemmas yields the claimed result. ■

Theorem (`coe_stepFin`). For the objects in step fin, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for step fin and applying the preceding component lemmas yields the claimed result. ■

Theorem (`coe_foldl_stepFin`). For the objects in foldl step fin, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for foldl step fin and applying the preceding component lemmas yields the claimed result. ■

Theorem (`coe_evalFin`). Evaluating the automaton or finite transition system in eval fin yields the stated reachable state after reading the word.

Proof. Induction on the input word tracks the reachable states for eval fin; the accepting-state condition then gives the stated language. ■

Theorem (`denote_iff_evalFin`). Evaluating the automaton or finite transition system in denote iff eval fin yields the stated reachable state after reading the word.

Proof. Induction on the input word tracks the reachable states for denote iff eval fin; the accepting-state condition then gives the stated language. ■

Theorem (`diffNFA_evalFrom`). Evaluating the automaton or finite transition system in diff nfa eval from yields the stated reachable state after reading the word.

Proof. Induction on the input word tracks the reachable states for diff nfa eval from; the accepting-state condition then gives the stated language. ■

Theorem (`diffNFA_eval`). Evaluating the automaton or finite transition system in diff nfa eval yields the stated reachable state after reading the word.

Proof. Induction on the input word tracks the reachable states for diff nfa eval; the accepting-state condition then gives the stated language. ■

Theorem (`diffNFA_mem_accepts_iff`). Membership in diff nfa mem accepts iff is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of diff nfa mem accepts iff exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`exists_diff_word_short`). The language in diff word short is nonempty exactly when it accepts a word shorter than the number of available automaton states.

Proof. Repeatedly remove a loop from any longer accepting path for diff word short; finiteness of the state set guarantees a repeated state until a short accepted word remains. ■

Theorem (`subsetB_iff`). The condition subset b holds exactly when the finite witness condition holds.

Proof. Expand both conditions in subset b iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`interEqB_iff`). The intersection in inter eq b iff equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for inter eq b iff, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`example_722_equiv`). Scott's example example 722 equiv has the claimed language-theoretic or computability property.

Proof. Compare membership or numerical components in example 722 equiv; the defining equations reduce both sides to the same data. ■

Definition (`autStateCardFuelCharBody`). This is the one-step numerical recurrence computing the number of automaton states represented by an expression code.

Definition (`autStateCardFuelChar`). This fuel-bounded numerical function computes the automaton-state count associated with an expression code.

Definition (`c9b5_boolNat`). A Boolean digit is numerically encoded by zero or one.

Definition (`c9b5_encodeListBool`). The coding function c9b5 encode list bool assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`c9b5_sexprDepth`). The coded expression depth is computed recursively, with leaves of depth one and binary depth one plus the maximum child depth.

Definition (`c9b5_sexprGodelEncode`). The coding function c9b5 sexpr godel encode assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`capCode`). The coding function cap code assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`autStateCardFuelCharLookup`). The numerical characteristic function aut state card fuel char lookup encodes its Boolean or relational test by zero and one.

Definition (`subsetBoundChar`). The numerical characteristic function subset bound char encodes its Boolean or relational test by zero and one.

Definition (`subsetGuardChar`). The numerical characteristic function subset guard char encodes its Boolean or relational test by zero and one.

Definition (`matchesBCatG`). The bounded concatenation-search function tests all splits of a coded word using the preceding matching approximation.

Definition (`matchesBCatGLookup`). The lookup form unpacks a single paired argument and applies the bounded concatenation-search function.

Definition (`matchesBCharBody`). The numerical characteristic function matches bchar body encodes its Boolean or relational test by zero and one.

Definition (`matchesBChar`). This fuel-bounded characteristic function returns one exactly when the coded word matches the coded expression.

Definition (`decideNonemptyBChar`). The numerical characteristic function decide nonempty bchar encodes its Boolean or relational test by zero and one.

Definition (`consistentBChar`). The numerical characteristic function consistent bchar encodes its Boolean or relational test by zero and one.

Definition (`matchesBCharBodyLookup`). The numerical characteristic function matches bchar body lookup encodes its Boolean or relational test by zero and one.

Definition (`subsetBChar`). This bounded characteristic function tests inclusion between the languages denoted by two expression codes.

Definition (`interEqChar`). This bounded characteristic function tests equality between the languages denoted by two expression codes.

Definition (`c9b6_decodeListBool`). The decoding operation c9b6 decode list bool recovers the finite list, expression, or tagged value represented by its numerical input, returning failure when the code is malformed.

Theorem (`c9b5_decodeList_encodeListBool`). For the objects in c9b5 decode list encode list bool, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for c9b5 decode list encode list bool and applying the preceding component lemmas yields the claimed result. ■

Theorem (`c9b5_boolNat_injective`). The construction c9b5 bool nat injective sends equal outputs only from equal inputs.

Proof. Equality of two values of c9b5 bool nat injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`c9b5_decodeList_injective`). The construction c9b5 decode list injective sends equal outputs only from equal inputs.

Proof. Equality of two values of c9b5 decode list injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`c9b5_map_boolNat_eq_iff`). The condition c9b5 map bool nat eq holds exactly when the finite witness condition holds.

Proof. Expand both conditions in c9b5 map bool nat eq iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`c9b5_takeCode_encodeListBool`). For the objects in c9b5 take code encode list bool, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for c9b5 take code encode list bool and applying the preceding component lemmas yields the claimed result. ■

Theorem (`c9b5_dropCode_encodeListBool`). For the objects in c9b5 drop code encode list bool, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for c9b5 drop code encode list bool and applying the preceding component lemmas yields the claimed result. ■

Theorem (`c9b5_listEqChar_encodeListBool`). For the objects in c9b5 list eq char encode list bool, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for c9b5 list eq char encode list bool and applying the preceding component lemmas yields the claimed result. ■

Theorem (`autStateCardFuelCharBody_eq`). The value of aut state card fuel char body eq equals the value described by aut state card fuel char body eq.

Proof. Compare membership or numerical components in aut state card fuel char body eq; the defining equations reduce both sides to the same data. ■

Theorem (`autStateCardFuelChar_eq_autStateCard`). The value of aut state card fuel char equals the value described by aut state card.

Proof. Compare membership or numerical components in aut state card fuel char eq aut state card; the defining equations reduce both sides to the same data. ■

Theorem (`primrec_autStateCardFuelCharBody`). The numerical function aut state card fuel char body is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of aut state card fuel char body. ■

Theorem (`autStateCardFuelCharBody_local`). For the objects in aut state card fuel char body local, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for aut state card fuel char body local and applying the preceding component lemmas yields the claimed result. ■

Theorem (`matchesBCharBody_eq`). The value of matches bchar body eq equals the value described by matches bchar body eq.

Proof. Compare membership or numerical components in matches bchar body eq; the defining equations reduce both sides to the same data. ■

Theorem (`c9b5_matchesBCatG_char`). For the objects in c9b5 matches bcat g char, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for c9b5 matches bcat g char and applying the preceding component lemmas yields the claimed result. ■

Theorem (`matchesBChar_eq_one_iff`). The zero–one test matches bchar returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in matches bchar eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`primrec_matchesBCatG`). The numerical function matches bcat g is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of matches bcat g. ■

Theorem (`primrec_matchesBCharBody`). The numerical function matches bchar body is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of matches bchar body. ■

Theorem (`matchesBChar_le_one`). For every input, matches bchar takes one of the two values zero and one.

Proof. Each Boolean-valued component of matches bchar le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`matchesBCharBody_local`). For the objects in matches bchar body local, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for matches bchar body local and applying the preceding component lemmas yields the claimed result. ■

Theorem (`c9b6_allBinDigitsChar_encodeListBool`). For the objects in c9b6 all bin digits char encode list bool, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for c9b6 all bin digits char encode list bool and applying the preceding component lemmas yields the claimed result. ■

Theorem (`c9b6_encodeListBool_lt_codeBound`). The natural number c9b6 encode list bool lt code bound lies strictly below its finite bound.

Proof. Following the defining recursion for c9b6 encode list bool lt code bound and applying the preceding component lemmas yields the claimed result. ■

Theorem (`c9b6_boolNat_decide_eq`). The value of c9b6 bool nat decide eq equals the value described by c9b6 bool nat decide eq.

Proof. Compare membership or numerical components in c9b6 bool nat decide eq; the defining equations reduce both sides to the same data. ■

Theorem (`c9b6_encodeListBool_decodeListBool_of_allBin`). The hypotheses all bin imply c9b6 encode list bool decode list bool.

Proof. Following the defining recursion for c9b6 encode list bool decode list bool of all bin and applying the preceding component lemmas yields the claimed result. ■

Theorem (`c9b6_matchesBChar_of_allBin`). The hypotheses all bin imply c9b6 matches bchar.

Proof. Following the defining recursion for c9b6 matches bchar of all bin and applying the preceding component lemmas yields the claimed result. ■

Theorem (`decideNonemptyBChar_eq_one_iff`). The zero–one test decide nonempty bchar returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in decide nonempty bchar eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`c9b6_sexprGodelEncode_cap`). For the objects in c9b6 sexpr godel encode cap, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for c9b6 sexpr godel encode cap and applying the preceding component lemmas yields the claimed result. ■

Theorem (`subsetGuardChar_le_one`). For every input, subset guard char takes one of the two values zero and one.

Proof. Each Boolean-valued component of subset guard char le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`subsetBChar_eq_one_iff`). The zero–one test subset bchar returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in subset bchar eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`consistentBChar_eq_one_iff`). The zero–one test consistent bchar returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in consistent bchar eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`decideNonemptyBChar_le_one`). For every input, decide nonempty bchar takes one of the two values zero and one.

Proof. Each Boolean-valued component of decide nonempty bchar le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`consistentBChar_le_one`). For every input, consistent bchar takes one of the two values zero and one.

Proof. Each Boolean-valued component of consistent bchar le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`autStateCardFuelChar_fuelTable_eq`). The value of aut state card fuel char fuel table eq equals the value described by aut state card fuel char fuel table eq.

Proof. Compare membership or numerical components in aut state card fuel char fuel table eq; the defining equations reduce both sides to the same data. ■

Theorem (`interEqChar_eq_one_iff`). The zero–one test inter eq char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in inter eq char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`matchesBChar_fuelTable_eq`). The value of matches bchar fuel table eq equals the value described by matches bchar fuel table eq.

Proof. Compare membership or numerical components in matches bchar fuel table eq; the defining equations reduce both sides to the same data. ■

Theorem (`primrec_autStateCardFuelChar`). The numerical function aut state card fuel char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of aut state card fuel char. ■

Theorem (`primrec_autStateCardFuelCharLookup`). The numerical function aut state card fuel char lookup is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of aut state card fuel char lookup. ■

Theorem (`primrec_autStateCardFuelChar2`). The numerical function aut state card fuel char2 is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of aut state card fuel char2. ■

Theorem (`primrec_matchesBCatGLookup`). The numerical function matches bcat glookup is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of matches bcat glookup. ■

Theorem (`primrec_matchesBChar`). The numerical function matches bchar is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of matches bchar. ■

Theorem (`primrec_decideNonemptyBChar`). The numerical function decide nonempty bchar is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of decide nonempty bchar. ■

Theorem (`primrec_consistentBChar`). The numerical function consistent bchar is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of consistent bchar. ■

Theorem (`primrec_matchesBCharBodyLookup`). The numerical function matches bchar body lookup is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of matches bchar body lookup. ■

Theorem (`primrec_matchesBChar2`). The numerical function matches bchar2 is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of matches bchar2. ■

Theorem (`primrec_decideNonemptyBChar2`). The numerical function decide nonempty bchar2 is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of decide nonempty bchar2. ■

Theorem (`primrec_consistentBChar2`). The numerical function consistent bchar2 is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of consistent bchar2. ■

Theorem (`primrec_subsetBChar`). The numerical function subset bchar is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of subset bchar. ■

Theorem (`primrec_interEqChar`). The numerical function inter eq char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of inter eq char. ■

Theorem (`subsetBChar_le_one`). For every input, subset bchar takes one of the two values zero and one.

Proof. Each Boolean-valued component of subset bchar le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`interEqChar_le_one`). For every input, inter eq char takes one of the two values zero and one.

Proof. Each Boolean-valued component of inter eq char le one is zero or one, and the defining Boolean combination preserves that range. ■

Definition (`ConsistencyPresentation`). A consistency presentation consists of an enumeration of all neighbourhoods, proofs that the enumerated sets are neighbourhoods, surjectivity of the enumeration, and a recursive decision procedure for finite consistency.

4.8.54 Language presentation

Formal languages, coded by expressions, form a partially effectively given neighbourhood system.

Definition (`SsysX_default`). The default presented language is the universal language of all finite Boolean words.

Definition (`boolNat`). A Boolean value is represented by zero for false and one for true.

Theorem (`boolNat_eq_one_iff`). The zero–one test bool nat returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in bool nat eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`boolNat_zero_one`). For every input, bool nat takes one of the two values zero and one.

Proof. Each Boolean-valued component of bool nat zero one is zero or one, and the defining Boolean combination preserves that range. ■

Definition (`encodeListBool`). The coding function list bool assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`SExpr.encode`). The coding function encode assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`natBool`). A natural number decodes to false at zero, true at one, and fails at every larger number.

Definition (`decodeListBool`). The decoding operation list bool recovers the finite list, expression, or tagged value represented by its numerical input, returning failure when the code is malformed.

Definition (`decodeFuel`). The decoding operation fuel recovers the finite list, expression, or tagged value represented by its numerical input, returning failure when the code is malformed.

Definition (`SExpr.decode`). The decoding operation decode recovers the finite list, expression, or tagged value represented by its numerical input, returning failure when the code is malformed.

Definition (`SsysX`). An index denotes the decoded nonempty regular language when decoding succeeds and otherwise denotes the universal language.

Theorem (`SsysX_mem`). For the objects in ssys x mem, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for ssys x mem and applying the preceding component lemmas yields the claimed result. ■

Theorem (`decodeFuel_pair_cap_isSome_iff`). The condition decode fuel pair cap is some holds exactly when the finite witness condition holds.

Proof. Expand both conditions in fuel pair cap is some iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`decodeFuel_pair_cat_isSome_iff`). The condition decode fuel pair cat is some holds exactly when the finite witness condition holds.

Proof. Expand both conditions in fuel pair cat is some iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`decodeFuel_succ_cap`). At a successor input, fuel succ cap satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of fuel succ cap gives this equation immediately. ■

Theorem (`decodeFuel_succ_cat`). At a successor input, fuel succ cat satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of fuel succ cat gives this equation immediately. ■

Theorem (`decodeFuel_succ_junk`). At a successor input, fuel succ junk satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of fuel succ junk gives this equation immediately. ■

Theorem (`decodeFuel_succ_not_sigma`). At a successor input, fuel succ not sigma satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of fuel succ not sigma gives this equation immediately. ■

Theorem (`decodeFuel_succ_sigma`). At a successor input, fuel succ sigma satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of fuel succ sigma gives this equation immediately. ■

Theorem (`decodeFuel_succ_single`). At a successor input, fuel succ single satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of fuel succ single gives this equation immediately. ■

Theorem (`decodeListBool_encodeListBool`). For the objects in list bool encode list bool, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for list bool encode list bool and applying the preceding component lemmas yields the claimed result. ■

Theorem (`natBinDigit_of_natBool_some`). The hypotheses nat bool some imply nat bin digit.

Proof. Following the defining recursion for nat bin digit of nat bool some and applying the preceding component lemmas yields the claimed result. ■

Theorem (`natBool_isSome_iff`). The condition nat bool is some holds exactly when the finite witness condition holds.

Proof. Expand both conditions in nat bool is some iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`mapM_natBool_isSome_iff`). The condition map m nat bool is some holds exactly when the finite witness condition holds.

Proof. Expand both conditions in map m nat bool is some iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`decodeListBool_isSome_iff`). The condition decode list bool is some holds exactly when the finite witness condition holds.

Proof. Expand both conditions in list bool is some iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`decodeFuelOkChar_eq_one_iff`). The zero–one test decode fuel ok char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in fuel ok char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Definition (`safeDecodeActive`). The decoding operation safe decode active recovers the finite list, expression, or tagged value represented by its numerical input, returning failure when the code is malformed.

Theorem (`SsysX_eq_denote_safe`). The value of ssys x equals the value described by denote safe.

Proof. Compare membership or numerical components in ssys x eq denote safe; the defining equations reduce both sides to the same data. ■

Theorem (`safeDecodeActive_nonempty`). The set or language safe decode active nonempty has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in safe decode active nonempty and combine them using the defining construction. ■

Theorem (`consistentB_safe_sigma`). For the objects in consistent b safe sigma, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for consistent b safe sigma and applying the preceding component lemmas yields the claimed result. ■

Theorem (`consistentB_sigma_safe`). For the objects in consistent b sigma safe, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for consistent b sigma safe and applying the preceding component lemmas yields the claimed result. ■

Definition (`sexprDepth`). Expression depth is one at leaves and one plus the maximum depth of the two children at binary constructors.

Theorem (`decodeFuel_encode`). For the objects in fuel encode, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for fuel encode and applying the preceding component lemmas yields the claimed result. ■

Definition (`SExpr.index`). The coding function index assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Theorem (`SExpr.decode_index`). For the objects in index, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for index and applying the preceding component lemmas yields the claimed result. ■

Theorem (`SsysX_surj`). Every object in the target of ssys x surj is represented by some input.

Proof. Choose the finite code or canonical representative supplied by the target object; decoding that choice gives the required preimage for ssys x surj. ■

Definition (`ssysActive`). An index is active exactly when it decodes to an expression with nonempty denotation.

Theorem (`safeDecodeActive_inactive`). For the objects in safe decode active inactive, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for safe decode active inactive and applying the preceding component lemmas yields the claimed result. ■

Definition (`ssysConsistentB`). Two presentation indices are declared consistent automatically if either is inactive, and otherwise by testing consistency of their decoded expressions.

Theorem (`ssysConsistentB_iff`). The condition ssys consistent b holds exactly when the finite witness condition holds.

Proof. Expand both conditions in ssys consistent b iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`ssys_cons_positivity`). For the objects in ssys cons positivity, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for ssys cons positivity and applying the preceding component lemmas yields the claimed result. ■

Theorem (`ssys_inter_nonempty_iff_consistent`). The set or language ssys inter nonempty iff consistent has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in ssys inter nonempty iff consistent and combine them using the defining construction. ■

Theorem (`ssys_cons_iff`). The condition ssys cons holds exactly when the finite witness condition holds.

Proof. Expand both conditions in ssys cons iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`ssys_cons_char_iff`). The condition ssys cons char holds exactly when the finite witness condition holds.

Proof. Expand both conditions in ssys cons char iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`example_722_presentation_inst47`). Scott's example example 722 presentation inst47 has the claimed language-theoretic or computability property.

Proof. Following the defining recursion for example 722 presentation inst47 and applying the preceding component lemmas yields the claimed result. ■

Definition (`PartiallyEffectivelyGiven`). A neighbourhood system is partially effectively given when it admits a consistency presentation.

Theorem (`c9b5_encodeListBool_eq`). The value of c9b5 encode list bool eq equals the value described by c9b5 encode list bool eq.

Proof. Compare membership or numerical components in c9b5 encode list bool eq; the defining equations reduce both sides to the same data. ■

Theorem (`c9b5_sexprDepth_eq`). The value of c9b5 sexpr depth eq equals the value described by c9b5 sexpr depth eq.

Proof. Compare membership or numerical components in c9b5 sexpr depth eq; the defining equations reduce both sides to the same data. ■

Theorem (`c9b5_sexprGodelEncode_eq`). The value of c9b5 sexpr godel encode eq equals the value described by c9b5 sexpr godel encode eq.

Proof. Compare membership or numerical components in c9b5 sexpr godel encode eq; the defining equations reduce both sides to the same data. ■

Theorem (`decodeFuel_depth_le`). The element or numerical value fuel depth le lies below the bound in the theorem.

Proof. Following the defining recursion for fuel depth le and applying the preceding component lemmas yields the claimed result. ■

Theorem (`natBool_eq_some_iff`). The condition nat bool eq some holds exactly when the finite witness condition holds.

Proof. Expand both conditions in nat bool eq some iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`mapM_natBool_eq_some`). The value of map m nat bool equals the value described by some.

Proof. Compare membership or numerical components in map m nat bool eq some; the defining equations reduce both sides to the same data. ■

Theorem (`decodeListBool_eq_some`). The value of decode list bool equals the value described by some.

Proof. Compare membership or numerical components in list bool eq some; the defining equations reduce both sides to the same data. ■

Theorem (`decodeFuel_sound`). Every finite witness accepted by fuel sound determines a valid semantic relation.

Proof. Induction over the finite witness for fuel sound composes each valid step, producing the semantic relation at its endpoint. ■

Definition (`ssysActiveChar`). The numerical characteristic function ssys active char encodes its Boolean or relational test by zero and one.

Theorem (`primrec_ssysActiveChar`). The numerical function ssys active char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of ssys active char. ■

Theorem (`ssysActiveChar_eq_one_iff`). The zero–one test ssys active char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in ssys active char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`ssysActiveChar_le_one`). For every input, ssys active char takes one of the two values zero and one.

Proof. Each Boolean-valued component of ssys active char le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`ssysActive_exists_decode`). For the objects in ssys active exists decode, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for ssys active exists decode and applying the preceding component lemmas yields the claimed result. ■

Definition (`ssysCanonicalCode`). The coding function ssys canonical code assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`ssysConsChar`). The numerical characteristic function ssys cons char encodes its Boolean or relational test by zero and one.

Theorem (`ssysConsChar_eq_one_iff`). The zero–one test ssys cons char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in ssys cons char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`ssysConsChar_le_one`). For every input, ssys cons char takes one of the two values zero and one.

Proof. Each Boolean-valued component of ssys cons char le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`ssysConsChar_zero_one`). For every input, ssys cons char takes one of the two values zero and one.

Proof. Each Boolean-valued component of ssys cons char zero one is zero or one, and the defining Boolean combination preserves that range. ■

Definition (`ssysConsistentBChar`). The numerical characteristic function ssys consistent bchar encodes its Boolean or relational test by zero and one.

Theorem (`primrec_ssysConsistentBChar`). The numerical function ssys consistent bchar is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of ssys consistent bchar. ■

Theorem (`ssysConsistentBChar_eq_one_iff`). The zero–one test ssys consistent bchar returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in ssys consistent bchar eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`ssysConsistentBChar_le_one`). For every input, ssys consistent bchar takes one of the two values zero and one.

Proof. Each Boolean-valued component of ssys consistent bchar le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`ssysConsChar_eq_ssysConsistentBChar`). The value of ssys cons char equals the value described by ssys consistent bchar.

Proof. Compare membership or numerical components in ssys cons char eq ssys consistent bchar; the defining equations reduce both sides to the same data. ■

Theorem (`primrec_ssysConsChar`). The numerical function ssys cons char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of ssys cons char. ■

Definition (`ssysInterEqChar`). The numerical characteristic function ssys inter eq char encodes its Boolean or relational test by zero and one.

Theorem (`ssys_cons_char_eq_one_iff`). The zero–one test ssys cons char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. The consistency character is one exactly when the preceding positivity result supplies a common indexed refinement of the two neighbourhoods. ■

Theorem (`Ssys_cons_computable_of_primrec_ssysConsChar`). The relation ssys cons computable of primrec ssys cons char is recursively decidable.

Proof. Reduce the relation for ssys cons computable of primrec ssys cons char to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`Ssys_cons_computable`). The relation ssys cons computable is recursively decidable.

Proof. Reduce the relation for ssys cons computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Definition (`SsysPres`). The ssys pres is the computable presentation whose enumeration and decision procedures are those constructed above.

Theorem (`c9b5_boolNat_eq`). The value of c9b5 bool nat eq equals the value described by c9b5 bool nat eq.

Proof. Compare membership or numerical components in c9b5 bool nat eq; the defining equations reduce both sides to the same data. ■

Theorem (`ssysCanonicalCode_eq`). The value of ssys canonical code eq equals the value described by ssys canonical code eq.

Proof. Compare membership or numerical components in ssys canonical code eq; the defining equations reduce both sides to the same data. ■

Theorem (`sexprDepth_safeDecodeActive_le`). The element or numerical value sexpr depth safe decode active le lies below the bound in the theorem.

Proof. Following the defining recursion for sexpr depth safe decode active le and applying the preceding component lemmas yields the claimed result. ■

Theorem (`ssys_interEq_iff`). The intersection in ssys inter eq iff equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for ssys inter eq iff, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`ssysInterEqChar_le_one`). For every input, ssys inter eq char takes one of the two values zero and one.

Proof. Each Boolean-valued component of ssys inter eq char le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`ssysInterEqChar_eq_one_iff`). The zero–one test ssys inter eq char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in ssys inter eq char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`primrec_ssysInterEqChar`). The numerical function ssys inter eq char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of ssys inter eq char. ■

Theorem (`Ssys_interEq_computable`). The relation ssys inter eq computable is recursively decidable.

Proof. Use the same witnesses in both directions for ssys inter eq computable, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Ssys_partially_effectively_given`). For the objects in ssys partially effectively given, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for ssys partially effectively given and applying the preceding component lemmas yields the claimed result. ■

Theorem (`example_722_presentation`). Scott's example example 722 presentation has the claimed language-theoretic or computability property.

Proof. Following the defining recursion for example 722 presentation and applying the preceding component lemmas yields the claimed result. ■
