4.8.55 Exercise 7.22 — domain of formal languages

(For algebraists.) Let $\Sigma = \{0,1\}^*$ be the free semigroup. A new domain is constructed by defining a family of sets by the least fixed point theorem as follows:

$$S = \{\Sigma\} \cup \{\{\sigma\} \mid \sigma \in \Sigma\} \cup \{XY \mid X, Y \in S\} \cup \{X \cap Y \mid X, Y \in S \text{ and } X \cap Y \neq \emptyset\}.$$

Here we write: $XY = \{\sigma\tau \mid \sigma \in X \text{ and } \tau \in Y\}$.

Prove that S is an effectively given, positive neighbourhood system. (Hint: The sets in S are each "regular events" in the terminology of automata theory, and we have a decision method for the set algebra of regular events.)

Define multiplication on $|S|$ by

$$xy = \{Z \in S \mid \exists X \in x\, \exists Y \in y.\, XY \subseteq Z\},$$

and show $|S|$ becomes a semigroup with Σ embedded into $|S|$ by the homomorphism $\sigma \mapsto \{X \in S \mid \sigma \in X\}$.

Investigate some *infinite words* in S, say those defined by least fixed points such as: $\vec{\sigma} = \sigma\vec{\sigma}$ and $\vec{\sigma} = \vec{\sigma}\sigma$. Are these equations true:

$$\vec{\sigma}\vec{\sigma} = \vec{\sigma}, \quad \vec{\sigma}\vec{\sigma}\vec{\sigma} = \vec{\sigma}, \quad \vec{\sigma}\vec{1}\vec{\sigma}\vec{1} = \vec{\sigma}\vec{1},$$

and $\vec{01}\,\vec{01}\,\vec{01}\,\vec{01} = \vec{01}\,\vec{01}$?

Exercise_7_22.lean

@import "Exercise_7_22.lean"

The development is with the regular languages, regular-language codes, and language presentation peers.

Theorem (`example_722`). Concatenation of words is the product of their embeddings, the product of languages is associative, and a stream arrow is idempotent.

Proof. By the embedding of words, the associativity of the language product, and the idempotence of a stream arrow. ■

4.8.56 Graph map

The graph of a computable endomap of the powerset is a computable element of the function space.

Definition (`capMap`). The map cap map relates basic source and target neighbourhoods by the mathematical operation expressed in its defining relation.

Definition (`halfIter`). Repeated halving applies integer division by two the specified number of times.

Theorem (`halfIter_zero`). At input zero, half iter has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of half iter zero gives this equation immediately. ■

Definition (`bitAt`). The bit at position k of n is the remainder modulo two after halving n exactly k times.

Definition (`cupMap`). The map cup map relates basic source and target neighbourhoods by the mathematical operation expressed in its defining relation.

Definition (`sumSet`). The set sum set consists exactly of the elements admitted by its defining membership condition.

Theorem (`compl_inter_nbhd`). The construction compl inter nbhd preserves the specified intersection of sets or neighbourhoods.

Proof. Use the same witnesses in both directions for compl inter nbhd, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`compl_subset_compl_of_subset`). The hypotheses subset imply compl subset compl.

Proof. Following the defining recursion for compl subset compl of subset and applying the preceding component lemmas yields the claimed result. ■

Definition (`elemSet`). The set elem set consists exactly of the elements admitted by its defining membership condition.

Theorem (`mem_elemSet`). The element described by elem set belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for elem set is supplied directly by the defining membership condition. ■

Definition (`bitsCode`). The coding function bits code assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`bitsList`). The bits list is the finite list extracted from, or encoded by, the given numerical data.

Definition (`bitsStep`). The state transformer bits step performs one stage of the finite numerical computation encoded in its state.

Definition (`gMap`). The map g map relates basic source and target neighbourhoods by the mathematical operation expressed in its defining relation.

Definition (`funMap`). The map fun map relates basic source and target neighbourhoods by the mathematical operation expressed in its defining relation.

Definition (`nextCellStep`). The state transformer next cell step performs one stage of the finite numerical computation encoded in its state.

Definition (`orUpTo`). Starting from one number, successively insert the bits of the other through the specified bound.

Definition (`plusIdx`). The sum-set neighbourhood index is obtained by the bounded bitwise accumulation determined by the two input indices.

Definition (`plusStep`). The state transformer plus step performs one stage of the finite numerical computation encoded in its state.

Theorem (`sumSet_mono`). Enlarging the input sets in sum set mono can only enlarge its resulting set or element.

Proof. Transport every witness for sum set mono along the assumed inclusions; the same witness then belongs to the enlarged result. ■

Definition (`plusMap`). The map plus map relates basic source and target neighbourhoods by the mathematical operation expressed in its defining relation.

Definition (`tagStep`). The state transformer tag step performs one stage of the finite numerical computation encoded in its state.

Definition (`tagCode`). The coding function tag code assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`tagOfBits`). The set bits of an index are decoded as a finite list and nested as tags around a terminal value.

Definition (`GraphIdx`). The construction graph idx is obtained by recursive clauses on its finite inputs.

Theorem (`GraphIdx_mono`). Enlarging the input sets in graph idx mono can only enlarge its resulting set or element.

Proof. Transport every witness for graph idx mono along the assumed inclusions; the same witness then belongs to the enlarged result. ■

Definition (`graphMap`). The map graph map relates basic source and target neighbourhoods by the mathematical operation expressed in its defining relation.

Definition (`unnumPair`). Iterating the successor-cell operation reconstructs the pair encoded by the inverse numerical enumeration.

Definition (`unnum1`). The first inverse-enumeration coordinate is the first component of the reconstructed pair.

Definition (`unnum2`). The second inverse-enumeration coordinate is the second component of the reconstructed pair.

Definition (`untagRef`). A tagged natural number is decoded recursively into its finite list of tags and terminal value.

Definition (`untagStep`). The state transformer untag step performs one stage of the finite numerical computation encoded in its state.

Definition (`untagState`). The bounded tag-decoding state is obtained by iterating the tag-removal transition sufficiently many times.

Definition (`untagList`). The untag list is the finite list extracted from, or encoded by, the given numerical data.

Definition (`untagVal`). The terminal value of a tagged code is extracted from the completed decoding state.

Theorem (`lt_of_testBit_true`). The hypotheses test bit true imply lt.

Proof. Following the defining recursion for lt of test bit true and applying the preceding component lemmas yields the claimed result. ■

Theorem (`halfIter_succ`). At a successor input, half iter succ satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of half iter succ gives this equation immediately. ■

Theorem (`primrec_halfIter`). The numerical function half iter is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of half iter. ■

Theorem (`primrec_bitAt`). The numerical function bit at is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of bit at. ■

Theorem (`bitAt_le_one`). For every input, bit at takes one of the two values zero and one.

Proof. Each Boolean-valued component of bit at le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`bitAt_eq_one_iff`). The zero–one test bit at returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in bit at eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`compl_nbhd`). For the objects in compl nbhd, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for compl nbhd and applying the preceding component lemmas yields the claimed result. ■

Theorem (`exists_combined_witness`). For the objects in combined witness, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for combined witness and applying the preceding component lemmas yields the claimed result. ■

Theorem (`mem_bitsList`). The element described by bits list belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for bits list is supplied directly by the defining membership condition. ■

Theorem (`nbhd_mem_iff_subset_elemSet`). Membership in nbhd mem iff subset elem set is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of nbhd mem iff subset elem set exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`elemSet_re_of_isComputableElement`). The map or element elem set re of is computable element is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for elem set re of is computable element to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`mem_decodeList_bitsCode`). The element described by list bits code belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for list bits code is supplied directly by the defining membership condition. ■

Theorem (`primrec_bitsStep`). The numerical function bits step is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of bits step. ■

Theorem (`bitsStep_unpair11`). For the objects in bits step unpair11, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for bits step unpair11 and applying the preceding component lemmas yields the claimed result. ■

Theorem (`bitsStep_unpair21`). For the objects in bits step unpair21, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for bits step unpair21 and applying the preceding component lemmas yields the claimed result. ■

Theorem (`bitsStep_unpair22`). For the objects in bits step unpair22, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for bits step unpair22 and applying the preceding component lemmas yields the claimed result. ■

Theorem (`bitsStep_iter_spec`). The numerical construction bits step iter spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for bits step iter spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`primrec_bitsCode`). The numerical function bits code is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of bits code. ■

Theorem (`isComputableElement_of_elemSet_re`). The relation element of elem set re is recursively decidable.

Proof. Reduce the relation for element of elem set re to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`isComputableElement_iff_elemSet_re`). The relation element iff elem set re is recursively decidable.

Proof. Reduce the relation for element iff elem set re to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`unnum_snd_lt_of_fst_succ`). At a successor input, unnum snd lt of fst succ satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of unnum snd lt of fst succ gives this equation immediately. ■

Theorem (`bitAt_swap_isComputable`). The map or element bit at swap is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for bit at swap is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`capMap_rel_iff`). The condition cap map rel holds exactly when the finite witness condition holds.

Proof. Expand both conditions in cap map rel iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`capMap_isComputable`). The map or element cap map is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for cap map is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`cupMap_rel_iff`). The condition cup map rel holds exactly when the finite witness condition holds.

Proof. Expand both conditions in cup map rel iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`cupMap_isComputable`). The map or element cup map is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for cup map is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`decodeList_injective`). The construction list injective sends equal outputs only from equal inputs.

Proof. Equality of two values of list injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`forall_rel_iff_subset_step`). The condition forall rel holds exactly when subset step holds.

Proof. Expand both conditions in rel iff subset step; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`gMap_rel_iff`). The condition g map rel holds exactly when the finite witness condition holds.

Proof. Expand both conditions in g map rel iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`graphMap_rel_iff`). The condition graph map rel holds exactly when the finite witness condition holds.

Proof. Expand both conditions in graph map rel iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`mem_bitsCodeList`). The element described by bits code list belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for bits code list is supplied directly by the defining membership condition. ■

Theorem (`mem_compl_nbhd`). The element described by compl nbhd belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for compl nbhd is supplied directly by the defining membership condition. ■

Theorem (`compl_nbhd_subset_Fun_iff`). The condition compl nbhd subset fun holds exactly when the finite witness condition holds.

Proof. Expand both conditions in compl nbhd subset fun iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`compl_nbhd_subset_iff`). The inclusion in compl nbhd subset iff holds exactly when the finite prefix, complement, or numerical condition on the right holds.

Proof. Translate both inclusions in compl nbhd subset iff into the relevant finite prefix or complement condition, and use antisymmetry for the converse direction. ■

Theorem (`mem_sumSet`). The element described by sum set belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for sum set is supplied directly by the defining membership condition. ■

Theorem (`nbhd_subset_iff_compl_subset_compl`). The inclusion in nbhd subset iff compl subset compl holds exactly when the finite prefix, complement, or numerical condition on the right holds.

Proof. Translate both inclusions in nbhd subset iff compl subset compl into the relevant finite prefix or complement condition, and use antisymmetry for the converse direction. ■

Theorem (`nbhd_subset_iff_myLor_eq`). The inclusion in nbhd subset iff my lor eq holds exactly when the finite prefix, complement, or numerical condition on the right holds.

Proof. Translate both inclusions in nbhd subset iff my lor eq into the relevant finite prefix or complement condition, and use antisymmetry for the converse direction. ■

Theorem (`nextCellStep_eq`). The value of next cell step eq equals the value described by next cell step eq.

Proof. Compare membership or numerical components in next cell step eq; the defining equations reduce both sides to the same data. ■

Theorem (`plusStep_unpair11`). For the objects in plus step unpair11, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for plus step unpair11 and applying the preceding component lemmas yields the claimed result. ■

Theorem (`plusStep_unpair12`). For the objects in plus step unpair12, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for plus step unpair12 and applying the preceding component lemmas yields the claimed result. ■

Theorem (`plusStep_unpair21`). For the objects in plus step unpair21, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for plus step unpair21 and applying the preceding component lemmas yields the claimed result. ■

Theorem (`plusStep_unpair22`). For the objects in plus step unpair22, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for plus step unpair22 and applying the preceding component lemmas yields the claimed result. ■

Theorem (`plusStep_iter_spec`). The numerical construction plus step iter spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for plus step iter spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`primrec_nextCellStep`). The numerical function next cell step is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of next cell step. ■

Theorem (`primrec_plusStep`). The numerical function plus step is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of plus step. ■

Theorem (`primrec_plusIdx`). The numerical function plus idx is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of plus idx. ■

Theorem (`primrec_tri`). The numerical function tri is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of tri. ■

Theorem (`primrec_num`). The numerical function num is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of num. ■

Theorem (`primrec_tagStep`). The numerical function tag step is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of tag step. ■

Theorem (`primrec_tagCode`). The numerical function tag code is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of tag code. ■

Theorem (`primrec_tagOfBits`). The numerical function tag of bits is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of tag of bits. ■

Theorem (`primrec_unnumPair`). The numerical function unnum pair is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of unnum pair. ■

Theorem (`primrec_unnum1`). The numerical function unnum1 is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of unnum1. ■

Theorem (`primrec_unnum2`). The numerical function unnum2 is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of unnum2. ■

Theorem (`primrec_untagStep`). The numerical function untag step is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of untag step. ■

Theorem (`primrec_untagState`). The numerical function untag state is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of untag state. ■

Theorem (`primrec_untagList`). The numerical function untag list is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of untag list. ■

Theorem (`primrec_untagVal`). The numerical function untag val is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of untag val. ■

Theorem (`tag_eq_foldr`). The value of tag equals the value described by foldr.

Proof. Compare membership or numerical components in tag eq foldr; the defining equations reduce both sides to the same data. ■

Theorem (`tag_eq_foldl_reverse`). The value of tag equals the value described by foldl reverse.

Proof. Compare membership or numerical components in tag eq foldl reverse; the defining equations reduce both sides to the same data. ■

Theorem (`tagCode_spec`). The numerical construction tag code spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for tag code spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`tagOfBits_spec`). The numerical construction tag of bits spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for tag of bits spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`testBit_orUpTo`). For the objects in test bit or up to, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for test bit or up to and applying the preceding component lemmas yields the claimed result. ■

Theorem (`testBit_orUpTo_self`). For the objects in test bit or up to self, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for test bit or up to self and applying the preceding component lemmas yields the claimed result. ■

Theorem (`plusIdx_testBit`). For the objects in plus idx test bit, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for plus idx test bit and applying the preceding component lemmas yields the claimed result. ■

Theorem (`compl_nbhd_plusIdx`). For the objects in compl nbhd plus idx, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for compl nbhd plus idx and applying the preceding component lemmas yields the claimed result. ■

Theorem (`plusMap_rel_iff`). The condition plus map rel holds exactly when the finite witness condition holds.

Proof. Expand both conditions in plus map rel iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`plusMap_isComputable`). The map or element plus map is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for plus map is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`unnumPair_spec`). The numerical construction unnum pair spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for unnum pair spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`unnum1_spec`). The numerical construction unnum1 spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for unnum1 spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`unnum2_spec`). The numerical construction unnum2 spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for unnum2 spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`untagList_bitAt_isComputable`). The map or element untag list bit at is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for untag list bit at is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`untagRef_succ_case`). At a successor input, untag ref succ case satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of untag ref succ case gives this equation immediately. ■

Theorem (`untagRef_zero_case`). For the objects in untag ref zero case, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for untag ref zero case and applying the preceding component lemmas yields the claimed result. ■

Theorem (`tag_untagRef`). For the objects in tag untag ref, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for tag untag ref and applying the preceding component lemmas yields the claimed result. ■

Theorem (`untagStep_cont`). For the objects in untag step cont, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for untag step cont and applying the preceding component lemmas yields the claimed result. ■

Theorem (`untagStep_done`). At input one, untag step has the value specified by its definition.

Proof. Following the defining recursion for untag step done and applying the preceding component lemmas yields the claimed result. ■

Theorem (`untagStep_halt`). For the objects in untag step halt, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for untag step halt and applying the preceding component lemmas yields the claimed result. ■

Theorem (`untagStep_of_done_iterate`). The hypotheses done iterate imply untag step.

Proof. Following the defining recursion for untag step of done iterate and applying the preceding component lemmas yields the claimed result. ■

Theorem (`untagStep_iter_spec`). The numerical construction untag step iter spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for untag step iter spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`untagState_spec`). The numerical construction untag state spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for untag state spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`decodeList_untagList`). For the objects in list untag list, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for list untag list and applying the preceding component lemmas yields the claimed result. ■

Theorem (`untagVal_and_isComputable`). The map or element untag val and is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for untag val and is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`untagVal_spec`). The numerical construction untag val spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for untag val spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`tag_untagList_untagVal`). For the objects in tag untag list untag val, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for tag untag list untag val and applying the preceding component lemmas yields the claimed result. ■

Theorem (`mem_Fun_compl_nbhd_iff`). Membership in fun compl nbhd iff is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of fun compl nbhd iff exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`mem_Fun_compl_nbhd_iff'`). Membership in fun compl nbhd iff' is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of fun compl nbhd iff' exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`mem_Fun_compl_nbhd_isComputable`). The map or element fun compl nbhd is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. The required witness for fun compl nbhd is computable is supplied directly by the defining membership condition. ■

Theorem (`mem_GraphIdx_iff`). Membership in graph idx iff is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of graph idx iff exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`graphIdx_isComputable`). The map or element graph idx is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for graph idx is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`graphMap_isComputable`). The map or element graph map is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for graph map is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`testBit_imp_mem_Fun_isComputable`). The map or element test bit imp mem fun is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for test bit imp mem fun is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`gMap_isComputable`). The map or element g map is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for g map is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`funMap_isComputable`). The map or element fun map is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for fun map is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

4.8.57 Exercise 7.23 — graph and fun computable

Complete the discussion of $P\mathbf{N}$ of Example 7.8. Show that the combinators fun and graph of Exercise 5.14 are computable. Also do the same for

$$\lambda x, y.\, x \cap y, \quad \lambda x, y.\, x \cup y, \quad \text{and } \lambda x, y.\, x + y,$$

where for $x, y \in P\mathbf{N}$ we define

$$x + y = \{n + m \mid n \in x \text{ and } m \in y\}.$$

What are the computable elements of $P\mathbf{N}$?

Exercise_7_23.lean

@import “Exercise_7_23.lean”

The development is with the graph map peer.

Theorem (`example_723`). The graph of the powerset endomap is a computable map into the powerset.

Proof. By the graph map. ■

4.8.58 LUCID histories

The domain of histories is effectively given, and the lifted connectives are computable.

Definition (`Gamma`). A history is either a finite list of natural numbers or an infinite stream of natural numbers.

Definition (`star`). The empty finite history is the distinguished initial history.

Definition (`streamCons`). Prefixing a number to a stream yields the stream whose first value is that number and whose later values are the original stream shifted by one place.

Theorem (`streamCons_zero`). At input zero, stream cons has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of stream cons zero gives this equation immediately. ■

Theorem (`streamCons_succ`). At a successor input, stream cons succ satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of stream cons succ gives this equation immediately. ■

Definition (`cons`). Prefixing a number to a history acts by list cons on finite histories and by stream cons on infinite histories.

Definition (`consSet`). The prefixed image of a set of histories consists of all histories obtained by prefixing the fixed number to a member of the set.

Theorem (`cons_injective`). The construction cons injective sends equal outputs only from equal inputs.

Proof. Equality of two values of cons injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`mem_consSet`). The element described by cons set belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for cons set is supplied directly by the defining membership condition. ■

Theorem (`consSet_empty`). The set or language in cons set empty is empty exactly under the stated absence-of-witness condition.

Proof. An element of the set in cons set empty would provide exactly the forbidden witness, while any such witness produces an element; hence emptiness is equivalent to its absence. ■

Theorem (`consSet_inter`). The construction cons set inter preserves the specified intersection of sets or neighbourhoods.

Proof. Use the same witnesses in both directions for cons set inter, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`consSet_inter_ne`). The construction cons set inter ne preserves the specified intersection of sets or neighbourhoods.

Proof. Use the same witnesses in both directions for cons set inter ne, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`consSet_nonempty`). The set or language cons set nonempty has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in cons set nonempty and combine them using the defining construction. ■

Theorem (`consSet_subset_of_subset`). The hypotheses subset imply cons set subset.

Proof. Following the defining recursion for cons set subset of subset and applying the preceding component lemmas yields the claimed result. ■

Theorem (`consSet_subset`). For the objects in cons set subset, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for cons set subset and applying the preceding component lemmas yields the claimed result. ■

Definition (`nbhd`). The neighbourhood determined by a finite list is the set of histories having that list as an initial segment.

Theorem (`nbhd_nil`). For the objects in nbhd nil, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for nbhd nil and applying the preceding component lemmas yields the claimed result. ■

Theorem (`nbhd_cons`). For the objects in nbhd cons, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for nbhd cons and applying the preceding component lemmas yields the claimed result. ■

Definition (`Lmem`). A set is an admissible history neighbourhood exactly when it is determined by some finite list.

Theorem (`mem_nbhd`). The element described by nbhd belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for nbhd is supplied directly by the defining membership condition. ■

Theorem (`L_nestedOrDisjoint`). The two objects compared in l nested or disjoint are distinct.

Proof. Following the defining recursion for l nested or disjoint and applying the preceding component lemmas yields the claimed result. ■

Definition (`L`). The history neighbourhood system has all histories as master set and the finite-prefix neighbourhoods as its neighbourhoods.

Definition (`Lenum`). The neighbourhood with index n is the prefix neighbourhood determined by the decoded list of n.

Theorem (`Lenum_mem`). For the objects in lenum mem, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for lenum mem and applying the preceding component lemmas yields the claimed result. ■

Theorem (`Lenum_surj`). Every object in the target of lenum surj is represented by some input.

Proof. Choose the finite code or canonical representative supplied by the target object; decoding that choice gives the required preimage for lenum surj. ■

Theorem (`Lenum_zero`). At input zero, lenum has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of lenum zero gives this equation immediately. ■

Definition (`isPrefixChar`). The numerical characteristic function is prefix char encodes its Boolean or relational test by zero and one.

Definition (`LenumConsChar`). The numerical characteristic function lenum cons char encodes its Boolean or relational test by zero and one.

Definition (`LenumConsCharP`). The numerical characteristic function lenum cons char p encodes its Boolean or relational test by zero and one.

Definition (`LenumInter`). For two neighbourhood indices, choose the index of the longer compatible prefix; when they are incompatible, choose the second index.

Definition (`LenumInterEqChar`). The numerical characteristic function lenum inter eq char encodes its Boolean or relational test by zero and one.

Definition (`LenumInterEqCharP`). The numerical characteristic function lenum inter eq char p encodes its Boolean or relational test by zero and one.

Theorem (`isPrefixChar_eq_one_iff`). The zero–one test is prefix char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in is prefix char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`isPrefixChar_le_one`). For every input, is prefix char takes one of the two values zero and one.

Proof. Each Boolean-valued component of is prefix char le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`isPrefixChar_eq_zero_or_one`). For every input, the characteristic function is prefix char is either zero or one.

Proof. The relevant clause of the recursive definition of is prefix char eq zero or one gives this equation immediately. ■

Theorem (`LenumConsChar_eq_one_iff`). The zero–one test lenum cons char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in lenum cons char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`LenumConsChar_le_one`). For every input, lenum cons char takes one of the two values zero and one.

Proof. Each Boolean-valued component of lenum cons char le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`LenumConsCharP_le_one`). For every input, lenum cons char p takes one of the two values zero and one.

Proof. Each Boolean-valued component of lenum cons char p le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`mulBit_eq_zero_or_one`). For every input, the characteristic function mul bit is either zero or one.

Proof. The relevant clause of the recursive definition of mul bit eq zero or one gives this equation immediately. ■

Theorem (`LenumInterEqChar_eq_one_iff`). The zero–one test lenum inter eq char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in lenum inter eq char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`LenumInterEqChar_le_one`). For every input, lenum inter eq char takes one of the two values zero and one.

Proof. Each Boolean-valued component of lenum inter eq char le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`LenumInterEqCharP_le_one`). For every input, lenum inter eq char p takes one of the two values zero and one.

Proof. Each Boolean-valued component of lenum inter eq char p le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`nbhd_nonempty`). The set or language nbhd nonempty has an element under the hypotheses of the theorem.

Proof. Choose witnesses from the nonempty input sets in nbhd nonempty and combine them using the defining construction. ■

Theorem (`primrec_isPrefixChar`). The numerical function is prefix char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of is prefix char. ■

Theorem (`primrec_LenumInterEqChar`). The numerical function lenum inter eq char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of lenum inter eq char. ■

Theorem (`primrec_LenumInterEqCharP`). The numerical function lenum inter eq char p is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of lenum inter eq char p. ■

Theorem (`primrec_isPrefixChar_swap`). The numerical function is prefix char swap is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of is prefix char swap. ■

Theorem (`primrec_LenumConsChar`). The numerical function lenum cons char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of lenum cons char. ■

Theorem (`primrec_LenumConsCharP`). The numerical function lenum cons char p is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of lenum cons char p. ■

Theorem (`primrec_LenumInter`). The numerical function lenum inter is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of lenum inter. ■

Theorem (`star_ne_cons`). The two objects compared in star ne cons are distinct.

Proof. Following the defining recursion for star ne cons and applying the preceding component lemmas yields the claimed result. ■

Theorem (`star_not_mem_consSet`). The two objects compared in star not mem cons set are distinct.

Proof. Following the defining recursion for star not mem cons set and applying the preceding component lemmas yields the claimed result. ■

Theorem (`nbhd_subset_iff`). The inclusion in nbhd subset iff holds exactly when the finite prefix, complement, or numerical condition on the right holds.

Proof. Translate both inclusions in nbhd subset iff into the relevant finite prefix or complement condition, and use antisymmetry for the converse direction. ■

Theorem (`Lenum_subset_iff`). The inclusion in lenum subset iff holds exactly when the finite prefix, complement, or numerical condition on the right holds.

Proof. Translate both inclusions in lenum subset iff into the relevant finite prefix or complement condition, and use antisymmetry for the converse direction. ■

Theorem (`Lenum_cons_iff`). The condition lenum cons holds exactly when the finite witness condition holds.

Proof. Expand both conditions in lenum cons iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`LenumInter_spec`). The construction lenum inter spec preserves the specified intersection of sets or neighbourhoods.

Proof. Use the same witnesses in both directions for lenum inter spec, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Lenum_cons_charP_eq_one_iff`). The zero–one test lenum cons char p returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in lenum cons char p eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`Lenum_cons_computable`). The relation lenum cons computable is recursively decidable.

Proof. Reduce the relation for lenum cons computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`nbhd_injective`). The construction nbhd injective sends equal outputs only from equal inputs.

Proof. Equality of two values of nbhd injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`Lenum_interEq_iff`). The intersection in lenum inter eq iff equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for lenum inter eq iff, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Lenum_interEq_charP_eq_one_iff`). The zero–one test lenum inter eq char p returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in lenum inter eq char p eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`Lenum_interEq_computable`). The relation lenum inter eq computable is recursively decidable.

Proof. Use the same witnesses in both directions for lenum inter eq computable, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Definition (`Lpres`). The lpres is the computable presentation whose enumeration and decision procedures are those constructed above.

Definition (`LFunData`). Function-space presentation data consists of numerical tests for inhabited step families, inclusion in each presentation, and equality in the codomain presentation, together with primitive-recursiveness proofs.

Theorem (`cons_inl`). For the objects in cons inl, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for cons inl and applying the preceding component lemmas yields the claimed result. ■

Theorem (`cons_inr`). For the objects in cons inr, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for cons inr and applying the preceding component lemmas yields the claimed result. ■

Theorem (`L_mem`). For the objects in l mem, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for l mem and applying the preceding component lemmas yields the claimed result. ■

Theorem (`L_master`). The master neighbourhood in l master is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for l master and applying the preceding component lemmas yields the claimed result. ■

Definition (`LenumSubsetChar`). The numerical characteristic function lenum subset char encodes its Boolean or relational test by zero and one.

Definition (`finPrefix`). The finite prefix of length n of a stream is the list of its values at positions below n.

Theorem (`finPrefix_zero`). The prefix of length zero of every stream is the empty list.

Proof. The relevant clause of the recursive definition of fin prefix zero gives this equation immediately. ■

Definition (`HasMin`). A history element has a minimum when one of its neighbourhoods is contained in every neighbourhood belonging to that element.

Definition (`bitToNat`). A Boolean value is encoded by zero for false and one for true.

Theorem (`bitToNat_false`). For the objects in bit to nat false, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for bit to nat false and applying the preceding component lemmas yields the claimed result. ■

Theorem (`bitToNat_true`). For the objects in bit to nat true, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for bit to nat true and applying the preceding component lemmas yields the claimed result. ■

Definition (`embStr`). A finite Boolean string is embedded as the list obtained by replacing false by zero and true by one.

Theorem (`embStr_nil`). For the objects in emb str nil, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for emb str nil and applying the preceding component lemmas yields the claimed result. ■

Definition (`Tenum`). The three canonical truth neighbourhoods are enumerated by the universal truth set, the false singleton, and the true singleton, with all later indices returning the universal set.

Theorem (`Tenum_zero`). At input zero, tenum has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of tenum zero gives this equation immediately. ■

Theorem (`Tenum_one`). At input one, tenum has the value specified by its definition.

Proof. The relevant clause of the recursive definition of tenum one gives this equation immediately. ■

Theorem (`Tenum_two`). At input two, tenum has the value specified by its definition.

Proof. The relevant clause of the recursive definition of tenum two gives this equation immediately. ■

Theorem (`Tenum_eq_canon`). The value of tenum equals the value described by canon.

Proof. Compare membership or numerical components in tenum eq canon; the defining equations reduce both sides to the same data. ■

Theorem (`Tenum_mem`). For the objects in tenum mem, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for tenum mem and applying the preceding component lemmas yields the claimed result. ■

Theorem (`Tenum_ne_empty`). The set or language in tenum ne empty is empty exactly under the stated absence-of-witness condition.

Proof. An element of the set in tenum ne empty would provide exactly the forbidden witness, while any such witness produces an element; hence emptiness is equivalent to its absence. ■

Theorem (`Tenum_surj`). Every object in the target of tenum surj is represented by some input.

Proof. Choose the finite code or canonical representative supplied by the target object; decoding that choice gives the required preimage for tenum surj. ■

Definition (`TeqChar`). The numerical characteristic function teq char encodes its Boolean or relational test by zero and one.

Definition (`TinterCode`). The coding function tinter code assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`andCode`). The coding function and code assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`andFn`). Conjunction on truth neighbourhoods returns its second argument on the false neighbourhood and the universal neighbourhood otherwise.

Theorem (`andFn_zero`). At input zero, and fn has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of and fn zero gives this equation immediately. ■

Theorem (`eq_master_of_master_subset`). The master neighbourhood in eq master of master subset is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for eq master of master subset and applying the preceding component lemmas yields the claimed result. ■

Theorem (`exists_cons_prefix_of_prefix_of_length_lt`). A proper finite prefix can be extended by one entry while remaining a prefix of the longer list.

Proof. The standard length laws for ranges, maps, append, and singleton lists compute the length in cons prefix of prefix of length lt. ■

Theorem (`exists_extend_of_not_hasMin`). The hypotheses not has min imply exists extend.

Proof. Following the defining recursion for extend of not has min and applying the preceding component lemmas yields the claimed result. ■

Definition (`buildData`). For a nonprincipal history element, recursively choose an increasing sequence of finite prefixes whose neighbourhoods belong to the element.

Theorem (`finPrefix_length`). The prefix of length n of a stream has length n.

Proof. The standard length laws for ranges, maps, append, and singleton lists compute the length in fin prefix length. ■

Theorem (`finPrefix_succ`). The prefix of length n+1 is the prefix of length n followed by the nth stream entry.

Proof. The relevant clause of the recursive definition of fin prefix succ gives this equation immediately. ■

Theorem (`finPrefix_prefix_succ`). Every finite stream prefix is a prefix of the next longer finite stream prefix.

Proof. The relevant clause of the recursive definition of fin prefix prefix succ gives this equation immediately. ■

Theorem (`finPrefix_prefix_of_le`). If n is at most m, the prefix of length n is a prefix of the prefix of length m.

Proof. Following the defining recursion for fin prefix prefix of le and applying the preceding component lemmas yields the claimed result. ■

Theorem (`finPrefix_take`). Taking the first n entries of the prefix of length m, when n is at most m, gives the prefix of length n.

Proof. Following the defining recursion for fin prefix take and applying the preceding component lemmas yields the claimed result. ■

Theorem (`master_ne_one_T`). The master neighbourhood in master ne one t is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for master ne one t and applying the preceding component lemmas yields the claimed result. ■

Theorem (`master_ne_zero_T`). The master neighbourhood in master ne zero t is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for master ne zero t and applying the preceding component lemmas yields the claimed result. ■

Theorem (`andFn_master`). The master neighbourhood in and fn master is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for and fn master and applying the preceding component lemmas yields the claimed result. ■

Theorem (`nbhd_finPrefix_antitone`). Longer finite stream prefixes determine smaller neighbourhoods.

Proof. Following the defining recursion for nbhd fin prefix antitone and applying the preceding component lemmas yields the claimed result. ■

Definition (`notCode`). The coding function not code assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`notFn`). Negation fixes the universal truth neighbourhood and exchanges the false and true singleton neighbourhoods.

Theorem (`notFn_master`). The master neighbourhood in not fn master is the universal set and satisfies the claimed relation.

Proof. Following the defining recursion for not fn master and applying the preceding component lemmas yields the claimed result. ■

Theorem (`notFn_zero`). At input zero, not fn has the initial value specified by its definition.

Proof. The relevant clause of the recursive definition of not fn zero gives this equation immediately. ■

Definition (`LFunData.ofPresentation`). The of presentation is the computable presentation whose enumeration and decision procedures are those constructed above.

Theorem (`one_inter_zero_T`). The construction one inter zero t preserves the specified intersection of sets or neighbourhoods.

Proof. Use the same witnesses in both directions for one inter zero t, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Definition (`postcompose`). Postcomposition sends a function element to its composite with the fixed approximable map.

Definition (`LFunData.pres`). The pres is the computable presentation whose enumeration and decision procedures are those constructed above.

Theorem (`primrec_TeqChar`). The numerical function teq char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of teq char. ■

Theorem (`primrec_TinterCode`). The numerical function tinter code is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of tinter code. ■

Theorem (`principal_hasMin`). For the objects in principal has min, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for principal has min and applying the preceding component lemmas yields the claimed result. ■

Definition (`pwArg`). The pointwise binary argument map rearranges a function and an input pair into the pair of arguments required for evaluation.

Definition (`pwFst`). The first pointwise projection evaluates the first function at the supplied argument.

Definition (`pwSnd`). The second pointwise projection evaluates the second function at the supplied argument.

Definition (`pointwiseBin`). A binary operation on the codomain lifts pointwise to a binary operation on function elements by evaluating both functions and then applying the operation.

Definition (`streamElement`). The element stream element is determined by the admissible neighbourhoods satisfying its defining membership condition.

Theorem (`finPrefix_eq_of_streamElement_eq`). Equal stream elements have equal finite prefixes at every length.

Proof. Compare membership or numerical components in fin prefix eq of stream element eq; the defining equations reduce both sides to the same data. ■

Theorem (`streamElement_injective`). The construction stream element injective sends equal outputs only from equal inputs.

Proof. Equality of two values of stream element injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`streamElement_not_hasMin`). The two objects compared in stream element not has min are distinct.

Proof. Following the defining recursion for stream element not has min and applying the preceding component lemmas yields the claimed result. ■

Theorem (`subset_iff_eq_or_eq_master`). The inclusion in subset iff eq or eq master holds exactly when the finite prefix, complement, or numerical condition on the right holds.

Proof. Translate both inclusions in subset iff eq or eq master into the relevant finite prefix or complement condition, and use antisymmetry for the converse direction. ■

Definition (`toElement`). The element to element is determined by the admissible neighbourhoods satisfying its defining membership condition.

Theorem (`toElement_injective`). The construction to element injective sends equal outputs only from equal inputs.

Proof. Equality of two values of to element injective determines their outer form and then each component, so the original inputs coincide. ■

Definition (`toStream`). A nonprincipal history element determines the stream whose finite prefixes are selected by its recursively constructed prefix chain.

Theorem (`buildData_succ`). At a successor input, build data succ satisfies its recursive step equation.

Proof. The relevant clause of the recursive definition of build data succ gives this equation immediately. ■

Theorem (`buildData_eq_finPrefix`). The list selected at stage n of the nonminimal-element construction is the length-n prefix of its selected stream.

Proof. Compare membership or numerical components in build data eq fin prefix; the defining equations reduce both sides to the same data. ■

Theorem (`mem_nbhd_finPrefix_toStream`). The element described by nbhd fin prefix to stream belongs to the set or neighbourhood specified by its hypotheses.

Proof. The required witness for nbhd fin prefix to stream is supplied directly by the defining membership condition. ■

Theorem (`exists_finPrefix_subset_of_mem`). Every neighbourhood of a nonminimal history element contains a finite-prefix neighbourhood of its selected stream.

Proof. Following the defining recursion for fin prefix subset of mem and applying the preceding component lemmas yields the claimed result. ■

Theorem (`toElement_surjective`). Every object in the target of to element surjective is represented by some input.

Proof. Choose the finite code or canonical representative supplied by the target object; decoding that choice gives the required preimage for to element surjective. ■

Theorem (`toElement_bijective`). The construction to element bijective is both injective and surjective.

Proof. Combine the injectivity and surjectivity results already proved for to element bijective. ■

Definition (`gammaEquivElement`). The element gamma equiv element is determined by the admissible neighbourhoods satisfying its defining membership condition.

Theorem (`zero_inter_one_T`). The construction zero inter one t preserves the specified intersection of sets or neighbourhoods.

Proof. Use the same witnesses in both directions for zero inter one t, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Tenum_inter_eq`). The intersection in tenum inter eq equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for tenum inter eq, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Tenum_inter_eq_TinterCode'`). The intersection in tenum inter eq tinter code' equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for tenum inter eq tinter code', combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Tenum_inter_eq_TinterCode`). The intersection in tenum inter eq tinter code equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for tenum inter eq tinter code, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Tpres_cons_iff`). The condition tpres cons holds exactly when the finite witness condition holds.

Proof. Expand both conditions in tpres cons iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`Tpres_cons_computable`). The relation tpres cons computable is recursively decidable.

Proof. Reduce the relation for tpres cons computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`zero_ne_one_T`). The two objects compared in zero ne one t are distinct.

Proof. Following the defining recursion for zero ne one t and applying the preceding component lemmas yields the claimed result. ■

Theorem (`Tenum_injOn`). The construction tenum inj on sends equal outputs only from equal inputs.

Proof. Following the defining recursion for tenum inj on and applying the preceding component lemmas yields the claimed result. ■

Theorem (`Tenum_interEq_iff`). The intersection in tenum inter eq iff equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for tenum inter eq iff, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Tenum_interEq_iff'`). The intersection in tenum inter eq iff' equals the indexed neighbourhood or language exactly under the stated finite comparison condition.

Proof. Use the same witnesses in both directions for tenum inter eq iff', combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Theorem (`Tpres_interEq_computable`). The relation tpres inter eq computable is recursively decidable.

Proof. Use the same witnesses in both directions for tpres inter eq computable, combining their inclusion proofs pointwise and using nonemptiness where intersection closure requires it. ■

Definition (`Tpres`). The tpres is the computable presentation whose enumeration and decision procedures are those constructed above.

Definition (`LTdata`). The function-space presentation from histories to truth values is assembled from the effective presentations of the history and truth domains.

Definition (`LTpres`). The ltpres is the computable presentation whose enumeration and decision procedures are those constructed above.

Theorem (`andFn_one`). At input one, and fn has the value specified by its definition.

Proof. The relevant clause of the recursive definition of and fn one gives this equation immediately. ■

Theorem (`andFn_mem`). For the objects in and fn mem, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for and fn mem and applying the preceding component lemmas yields the claimed result. ■

Definition (`andMap2`). The map and map2 relates basic source and target neighbourhoods by the mathematical operation expressed in its defining relation.

Definition (`andT`). Truth conjunction is the approximable map induced by conjunction on truth neighbourhoods.

Theorem (`notFn_one`). At input one, not fn has the value specified by its definition.

Proof. The relevant clause of the recursive definition of not fn one gives this equation immediately. ■

Theorem (`notFn_mem`). For the objects in not fn mem, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for not fn mem and applying the preceding component lemmas yields the claimed result. ■

Definition (`notT`). Truth negation is the approximable map induced by negation on truth neighbourhoods.

Theorem (`bitToNat_injective`). The construction bit to nat injective sends equal outputs only from equal inputs.

Proof. Equality of two values of bit to nat injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`embStr_cons`). For the objects in emb str cons, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for emb str cons and applying the preceding component lemmas yields the claimed result. ■

Theorem (`embStr_prefix_iff`). One Boolean string is a prefix of another exactly when its numerical embedding is a prefix of the other embedding.

Proof. Expand both conditions in emb str prefix iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`cone_subset_cone_iff_nbhd_embStr`). The condition cone subset cone holds exactly when nbhd emb str holds.

Proof. Expand both conditions in cone subset cone iff nbhd emb str; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`sigmaBot_le_iff_toElement_inl_embStr`). The condition sigma bot le holds exactly when to element inl emb str holds.

Proof. Expand both conditions in sigma bot le iff to element inl emb str; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`primrec_notCode`). The numerical function not code is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of not code. ■

Theorem (`notFn_Tenum`). For the objects in not fn tenum, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for not fn tenum and applying the preceding component lemmas yields the claimed result. ■

Theorem (`notT_isComputable`). The map or element not t is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for not t is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`primrec_andCode`). The numerical function and code is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of and code. ■

Theorem (`andFn_Tenum`). For the objects in and fn tenum, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for and fn tenum and applying the preceding component lemmas yields the claimed result. ■

Theorem (`andT_isComputable`). The map or element and t is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for and t is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`postcompose_isComputable`). The map or element postcompose is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for postcompose is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`pointwiseBin_isComputable`). The map or element pointwise bin is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for pointwise bin is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`notT_lifted_isComputable`). The map or element not t lifted is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for not t lifted is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`andT_lifted_isComputable`). The map or element and t lifted is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for and t lifted is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`deMorganT_isComputable`). The map or element de morgan t is computable is computable with respect to the presentations appearing in its domain and codomain.

Proof. Reduce the relation for de morgan t is computable to the previously constructed primitive-recursive characteristic functions and close recursive decidability under the required Boolean operations. ■

Theorem (`Gamma_cases`). For the objects in gamma cases, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for gamma cases and applying the preceding component lemmas yields the claimed result. ■

Theorem (`L_isEffectivelyGiven`). For the objects in l is effectively given, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for l is effectively given and applying the preceding component lemmas yields the claimed result. ■

Theorem (`LenumSubsetChar_le_one`). For every input, lenum subset char takes one of the two values zero and one.

Proof. Each Boolean-valued component of lenum subset char le one is zero or one, and the defining Boolean combination preserves that range. ■

Theorem (`Lenum_subset_char_eq_one_iff`). The zero–one test lenum subset char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in lenum subset char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`T_isEffectivelyGiven`). For the objects in t is effectively given, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for t is effectively given and applying the preceding component lemmas yields the claimed result. ■

Theorem (`TeqChar_eq_one_iff`). The zero–one test teq char returns one exactly when the mathematical condition encoded in its definition holds.

Proof. Separate the possible zero–one values occurring in teq char eq one iff; the value one survives precisely in the case described by the defining predicate. ■

Theorem (`embStr_injective`). The construction emb str injective sends equal outputs only from equal inputs.

Proof. Equality of two values of emb str injective determines their outer form and then each component, so the original inputs coincide. ■

Theorem (`primrec_LenumSubsetChar`). The numerical function lenum subset char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of lenum subset char. ■

Theorem (`Lenum_subset_recDecidable`). The relation lenum subset rec decidable is recursively decidable.

Proof. Following the defining recursion for lenum subset rec decidable and applying the preceding component lemmas yields the claimed result. ■

Definition (`codePair`). The coding function code pair assigns its finite list, expression, pair, or tagged value a natural-number index by pairing and list coding.

Definition (`chainDec`). A decoded finite list is an admissible fixed-point chain when its first member is the bottom code and each later member is included in the image of its predecessor.

Definition (`fixPStep`). The state transformer fix pstep performs one stage of the finite numerical computation encoded in its state.

Definition (`fixStp`). One fixed-point search step updates the accumulated chain code and current candidate according to the inclusion characteristic.

Definition (`fixChainChar`). The numerical characteristic function fix chain char encodes its Boolean or relational test by zero and one.

Definition (`gLastOf`). The last element of a nonempty coded chain is returned, with zero used for the empty chain.

Definition (`gStepsOK`). The state transformer g steps ok performs one stage of the finite numerical computation encoded in its state.

Theorem (`Xenum_codePair`). For the objects in xenum code pair, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for xenum code pair and applying the preceding component lemmas yields the claimed result. ■

Theorem (`fixPStep_foldl_fst`). For the objects in fix pstep foldl fst, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for fix pstep foldl fst and applying the preceding component lemmas yields the claimed result. ■

Theorem (`fixPStep_foldl_snd`). For the objects in fix pstep foldl snd, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for fix pstep foldl snd and applying the preceding component lemmas yields the claimed result. ■

Theorem (`fixStp_eq`). The value of fix stp eq equals the value described by fix stp eq.

Proof. Compare membership or numerical components in fix stp eq; the defining equations reduce both sides to the same data. ■

Theorem (`fixChainChar_eq`). The value of fix chain char eq equals the value described by fix chain char eq.

Proof. Compare membership or numerical components in fix chain char eq; the defining equations reduce both sides to the same data. ■

Theorem (`fixChainChar_spec`). The numerical construction fix chain char spec computes exactly the finite object described by its specification.

Proof. Induction over the bounded iteration for fix chain char spec maintains the recorded accumulator invariant and yields the claimed final components. ■

Theorem (`gStepsOK_complete`). Every semantic relation in g steps ok complete has a finite witness of the prescribed form.

Proof. Induction over the semantic iteration for g steps ok complete selects an index for each intermediate neighbourhood and assembles the finite witness. ■

Theorem (`gStepsOK_sound`). Every finite witness accepted by g steps ok sound determines a valid semantic relation.

Proof. Induction over the finite witness for g steps ok sound composes each valid step, producing the semantic relation at its endpoint. ■

Theorem (`fixElement_mem_iff_chain`). Membership in fix element mem iff chain is equivalent to the explicit witness condition given by the construction.

Proof. Expanding the membership definition of fix element mem iff chain exposes exactly the witnesses and equations occurring on the other side. ■

Theorem (`fixMap_rel_iff`). The condition fix map rel holds exactly when the finite witness condition holds.

Proof. Expand both conditions in fix map rel iff; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`leastMap_Xenum_rel`). For the objects in least map xenum rel, the named equality, inclusion, or finite-witness relation holds.

Proof. Following the defining recursion for least map xenum rel and applying the preceding component lemmas yields the claimed result. ■

Theorem (`chainDec_iff_gStepsOK`). The condition chain dec holds exactly when g steps ok holds.

Proof. Expand both conditions in chain dec iff g steps ok; their witnesses correspond in both directions by the defining equations and the established coding identities. ■

Theorem (`primrec_fixStp`). The numerical function fix stp is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of fix stp. ■

Theorem (`primrec_fixChainChar`). The numerical function fix chain char is primitive recursive.

Proof. Primitive recursion and closure under composition, pairing, bounded search, and the previously established component functions give primitive recursiveness of fix chain char. ■

4.8.59 Exercise 7.24 — LUCID history domain

(Suggested by the LUCID language of Ashcroft and Wadge: SIAM Jour. Comp. vol. 5 (1976).)
Define a set Γ by

$$\Gamma = \bigcup_{i=0}^{\infty} (\{i\} \times \Gamma) \cup \{\star\}.$$

Define a system

$$L = \{\Gamma\} \cup \{\{i\} \times X \mid i \in \mathbf{N} \text{ and } X \in L\}.$$

Show that L is effectively given. Show that the elements of $|L|$ can be identified with the finite and infinite sequences of natural numbers. What is the connection between B and L?

Show that the combinators of LUCID can be construed as computable mappings of type

$$(L \to T) \to (L \to T)$$

or of type

$$(L \to T) \times (L \to T) \to (L \to T).$$

Conclude that programs in LUCID define computable maps.

Exercise_7_24.lean

@import "Exercise_7_24.lean"

The development is with the LUCID histories peer.

Theorem (`example_724`). The domain of histories is effectively given, the lifted negation and conjunction are computable, and passage to an element is bijective.

Proof. By the presentation of histories. ■

4.9 Retracts of the universal domain

<!DOCTYPE svg PUBLIC "-//W3C//DTD SVG 1.1//EN" "http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd">

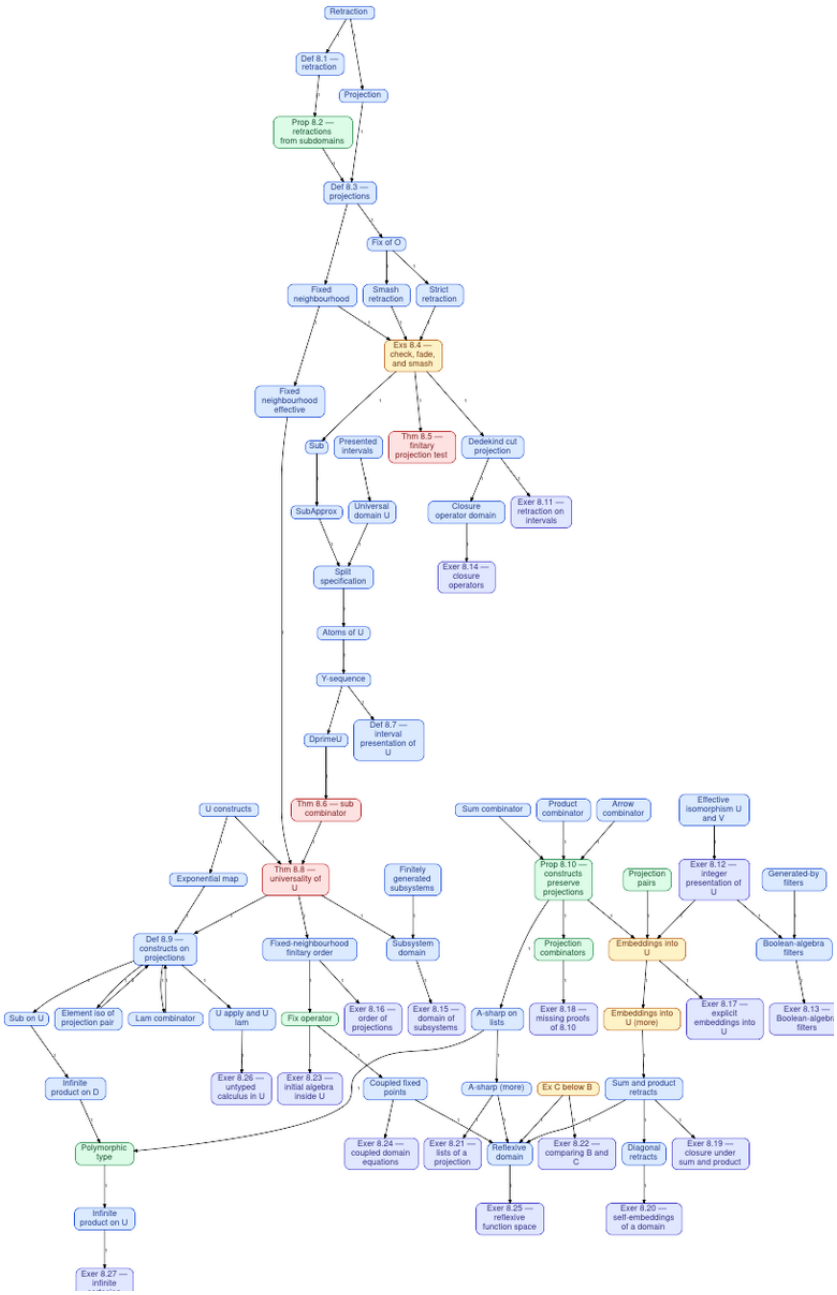

Figure 53: Diagram 18

4.9.1 Introduction

In order to be able to have a fully flexible method of solving domain equations and to be able to see why the domains obtained are effectively given, we shall embed all the desired domains in one “largest” domain. This universal domain will be easily shown to be effectively given, and the mappings needed to extract the other domains will be found to be computable. In order to be able to carry out this programme, we investigate first how certain subdomains correspond to mappings — the so-called *retracts*. An advantage of

this analysis is that all the necessary definitions can be written out in λ-calculus notation, thus demonstrating the power of our mathematical programming language.

4.9.2 Retraction

A retraction is an approximable endomap of a domain that is idempotent under composition. Every subdomain embedding yields such a retraction, whose fixed points recover the subdomain.

Definition (`Retraction`). An approximable map from a domain to itself is a retraction when its composite with itself equals itself.

Proof. By the defining field of the class. ■

Theorem (`isRetraction_idMap`). The identity map of a domain is a retraction.

Proof. By the left unit law for composition of approximable maps. ■

Definition (`Subsystem.retractionOfSubsystem`). From a subdomain embedding one forms the composite of the injection after the projection; that composite is the associated retraction of the ambient domain.

Proof. By the projection–injection presentation of a subdomain. ■

Theorem (`Subsystem.retractionOfSubsystem_rel`). Two neighbourhoods are related by the subdomain retraction precisely when there is a neighbourhood of the subdomain lying between them.

Proof. By unfolding the composite of injection and projection. ■

Theorem (`Subsystem.retractionOfSubsystem_toElementMap_inj`). The subdomain retraction fixes every point in the image of the injection.

Proof. By the projection–injection identity on the subdomain. ■

Definition (`Subsystem.elementIso`). Elements of a subdomain are order-isomorphic to the fixed points of its associated retraction.

Proof. The injection lands in the fixed-point set; the projection recovers the subdomain element; monotonicity of both maps gives the order isomorphism. ■

Theorem (`Subsystem.isRetraction_retractionOfSubsystem`). The endomap associated with a subdomain embedding is a retraction.

Proof. By the projection–injection identity and associativity of composition. ■

Theorem (`Subsystem.retraction_of_subsystem`). The subdomain endomap is a retraction, and the subdomain is isomorphic to its fixed-point set.

Proof. By the retraction property and the element isomorphism. ■

4.9.3 Definition 8.1 — retraction

DEFINITION 8.1. A retraction of a given domain E is an approximable mapping $a : E \to E$ such that $a \circ a = a$. □

The development is with the retraction peer.

Theorem (`definition_81`). An approximable endomap is a retraction precisely when it equals its composite with itself.

Proof. By the definition of retraction. ■

`Definition_8_1.lean`

```
module

public import DomainTheory.NeighbourhoodSystems.RetractsOfTheUniversalDomain.

  ⟨fun h => h.out, fun h => ⟨h⟩⟩

end DomainTheory.NeighbourhoodSystems
```

4.9.4 Proposition 8.2 — retractions from subdomains

PROPOSITION 8.2. If $D \triangleleft E$ and if $a : E \to E$ is defined by

$$X\ a\ Z \quad \text{iff} \quad \exists Y \in D.\ X \subseteq Y \subseteq Z$$

for all $X, Z \in E$, then a is a retraction and $|D|$ is isomorphic to the fixed-point set of a, the set $\{y \in |E| \mid a(y) = y\}$, under inclusion.

Proof: That a is an approximable mapping is a direct consequence of Definition 6.10. Indeed, in the notation of Proposition 6.12, we have

$$a = i \circ j,$$

and this is another proof that a is approximable. This remark is also convenient, since we know from 6.10

$$j \circ i = I_D.$$

Therefore, we find:

$$a \circ a = i \circ j \circ i \circ j = i \circ j = a;$$

and so a is a retraction.

We can also employ i and j to give the isomorphism on $|D|$. If $x \in |D|$, then $i(x) \in |E|$ and we calculate:

$$a(i(x)) = i \circ j \circ i(x) = i(x).$$

Thus, $i(x)$ belongs to the fixed-point set of a. In the other direction, if $a(y) = y$, then $i(j(y)) = y$. But $j(y) \in |D|$, so i maps $|D|$ one-one and onto the fixed-point set of a. As i and j are monotone, the map is an isomorphism with respect to $\sqsubseteq$. □

Not every retraction comes from a relationship like $D \triangleleft E$; in fact, we can see from the definition of a above that $a \sqsubseteq 1_E$. But, as is indicated in Exercise 8.11, even this condition is not sufficient to characterize the kind of retractions provided by 8.2. The characterization is as follows.

The development is with the retraction peer.

Theorem (`proposition_82`). For every subdomain embedding, the associated endomap is a retraction, and the subdomain's elements are isomorphic to that retraction's fixed points.

Proof. By the retraction and element-isomorphism facts for subdomain retractions. ■

4.9.5 Projection

A projection is a retraction lying below the identity. It is finitary when its fixed-point set is isomorphic to the element space of some neighbourhood system; in particular every subdomain retraction is a finitary projection.

Definition (`IsFinitary`). An endomap is finitary when the ordered set of its fixed points is isomorphic to the elements of some neighbourhood system.

Proof. By the defining existential. ■

Definition (`IsProjection`). An endomap is a projection when it is a retraction and lies below the identity.

Proof. By the defining conjunction. ■

Definition (`FinitaryProjection`). A finitary projection is a projection that is finitary.

Proof. By the defining fields of the class. ■

Theorem (`Subsystem.isFinitary_retractionOfSubsystem`). The retraction of a subdomain embedding is finitary.

Proof. The element isomorphism of the subdomain supplies the witnessing domain. ■

Theorem (`Subsystem.retractionOfSubsystem_le_idMap`). The subdomain retraction lies below the identity.

Proof. Related neighbourhoods of the retraction are nested, so the identity relation holds between them. ■

Theorem (`Subsystem.isProjection_retractionOfSubsystem`). The subdomain retraction is a projection.

Proof. By the retraction and identity-bound facts. ■

Theorem (`Subsystem.isFinitaryProjection_retractionOfSubsystem`). The subdomain retraction is a finitary projection.

Proof. By the projection and finitary facts. ■

4.9.6 Definition 8.3 — projections

DEFINITION 8.3. A retraction $a : E \to E$ is called a *projection* provided

$$a \sqsubseteq 1_E;$$

it is *finitary* iff its fixed-point set is isomorphic to a domain. □

The development is with the projection peer.

Theorem (`definition_83`). An endomap is a projection precisely when it is a retraction below the identity, and a finitary projection precisely when it is both a projection and finitary (fixed points isomorphic to a domain).

Proof. By the definitions of projection and finitary projection. ■

4.9.7 Fixed neighbourhood

The fixed-neighbourhood system of an approximable endomap collects neighbourhoods on which the map relates to itself; it is a subdomain. Compact elements agree with principals; a finitary projection is characterized by Scott's membership formula, proved by sectioning its fixed-point isomorphism.

Definition (`FixSet`). The fixed-point set of an endomap consists of those domain elements that the map sends to themselves.

Proof. By the subtype of fixed points. ■

Definition (`fixedNbhd`). The fixed neighbourhood system over the same index type admits a set precisely when it is a neighbourhood of the ambient system and the endomap relates that set to itself; the master is unchanged.

Proof. By the intersection and sub-master clauses inherited from the ambient system together with compositional closure of self-relation. ■

Theorem (`fixedNbhd_mem`). Membership in the fixed neighbourhood system is equivalent to ambient membership together with self-relation of the endomap on that set.

Proof. By definition. ■

Definition (`IsCompactElt`). An element is compact when whenever it lies below a directed supremum of elements, it lies below some term of that directed family.

Proof. By the universal quantification over directed families. ■

Theorem (`principal_le_of_mem`). The principal determined by a sub-neighbourhood on which an element lies is below that element.

Proof. By upward closure along inclusion of neighbourhoods. ■

Theorem (`principalFamily_directed`). The principals obtained from neighbourhoods on which an element lies form a directed family.

Proof. By intersection of witnessing neighbourhoods and the principal comparison lemma. ■

Theorem (`eq_iSupDirected_principal`). Every element equals the directed supremum of the principals from its witnessing neighbourhoods.

Proof. By element extension and the directed-supremum membership characterization. ■

Theorem (`eq_principal_of_isCompactElt`). Every compact element is a principal.

Proof. By directedness of the principal family and compactness against that supremum. ■

Theorem (`principal_compact`). A principal below a directed supremum lies below some term of the family.

Proof. By membership at the principal's neighbourhood and the directed supremum membership law. ■

Theorem (`principal_isCompactElt`). Principals are compact elements.

Proof. By the principal compactness lemma. ■

Theorem (`fixedNbhd_subsystem`). The fixed neighbourhood system embeds as a subdomain of the ambient system.

Proof. By master coincidence, inheritance of membership, and intersection closure for self-relation. ■

Theorem (`mem_of_exists_rel_self`). If an element lies in a neighbourhood contained in a larger one and the endomap self-relates on some inner neighbourhood, then the image element lies in the larger neighbourhood.

Proof. By principal comparison, monotonicity of the element map, and upward closure. ■

Theorem (`isFinitaryProjection_of_formula`). An endomap satisfying Scott's membership formula on elements is a finitary projection.

Proof. By identifying it with the subdomain retraction of its fixed neighbourhood system and applying the subdomain finitary projection theorem. ■

Definition (`sectionMap`). From an order-isomorphism between the fixed-point set and another domain, the section map sends a principal in the codomain to the corresponding fixed point in the ambient domain.

Proof. By monotonic extension from principals. ■

Theorem (`toElementMap_iSupDirected_fixed`). On a directed family of fixed points, the element map of the endomap preserves the directed supremum.

Proof. By the fixed-point hypothesis and the directed supremum law for element maps. ■

Theorem (`toElementMap_sectionMap_principal`). The section map carries a codomain principal to the underlying fixed point of its inverse image under the isomorphism.

Proof. By the defining action on principals. ■

Theorem (`toElementMap_sectionMap`). The section map on an arbitrary codomain element equals the directed supremum of sections on the principals below it.

Proof. By principal decomposition, fixed points along that family, and antisymmetry using monotonicity of the isomorphism. ■

Theorem (`e_apply_iSupDirected_fixed`). Under fixed-point and directedness hypotheses, applying the fixed-point isomorphism to a supremum of fixed points equals the supremum of the corresponding codomain elements.

Proof. By monotonicity of the isomorphism and preservation of directed suprema on fixed points. ■

Theorem (`toElementMap_idem`). For a retraction, applying the element map twice equals applying it once.

Proof. By idempotence of composition of approximable maps. ■

Theorem (`exists_principal_eq_of_isRetraction_le_idMap`). For a retraction below the identity, the section of a codomain principal is itself a principal.

Proof. By compactness of principals, preservation of directed suprema under the isomorphism, and the retraction below the identity. ■

Theorem (`formula_of_isFinitaryProjection`). Every finitary projection satisfies Scott's membership formula: an element's image lies in a neighbourhood if and only if that neighbourhood is admissible and some inner neighbourhood on which the element lies and the map self-relates is contained in it.

Proof. By the subsection construction, principal factorization on the fixed-point domain, and the membership transfer lemmas. ■

Theorem (`finitaryProjection_iff_formula`). An endomap is a finitary projection if and only if it satisfies Scott's membership formula for every element.

Proof. By the two directions of the formula characterisation. ■

4.9.8 Fix of O

The two-element system O, together with check and fade, realizes the first half of Examples 8.4: a retraction onto O whose fixed points are order-isomorphic to O when a non-bottom anchor u is chosen.

Theorem (`fin2_zero_subset_zero_one`). The singleton $\{0\}$ on two labels is contained in $\{0, 1\}$.

Proof. By membership of 0. ■

Theorem (`fin2_zero_ne_zero_one`). The singleton $\{0\}$ is not the full master $\{0, 1\}$.

Proof. By membership of 1. ■

Definition (`O`). The two-element neighbourhood system admits exactly the singleton $\{0\}$ and the master $\{0, 1\}$.

Proof. By case analysis on intersections and sub-master constraints. ■

Theorem (`O_master_eq`). The master of O is $\{0, 1\}$.

Proof. By definition. ■

Theorem (`O_mem_iff`). Membership in O is equivalent to being either $\{0\}$ or $\{0, 1\}$.

Proof. By definition. ■

Theorem (`O_mem_zero`). The singleton $\{0\}$ is a neighbourhood of O.

Proof. By the first disjunct. ■

Definition (`Otop`). The top element of O is the principal over $\{0\}$.

Proof. By the principal constructor. ■

Theorem (`mem_Otop`). A set lies in the top element exactly when it is an O-neighbourhood containing $\{0\}$.

Proof. By the principal membership law. ■

Definition (`check`). The check combinator relates a D-neighbourhood X to an O-neighbourhood Y when Y is the master or X is not the master of D.

Proof. By the relational axioms for approximable maps. ■

Theorem (`check_rel`). The check relation is equivalent to D-membership of X, O-membership of Y, and either Y is the master or X is proper.

Proof. By definition. ■

Theorem (`exists_mem_ne_master_of_ne_bot`). Every non-bottom element of D lies in some neighbourhood distinct from the master.

Proof. By contrapositive identification of bottom. ■

Definition (`fade2`). The binary fade relates the first factor in O, a D-neighbourhood, and a target neighbourhood so that either the target is the D-master or the O-factor is $\{0\}$ and the D-factor is contained in the target.

Proof. By the relational axioms for binary approximable maps. ■

Definition (`fade`). Fade on the product $O \times D$ is the curry of the binary fade.

Proof. By pairing of binary maps. ■

Definition (`a`). For a chosen anchor u in D, the endomap a is fade after pairing check with the constant map to u.

Proof. By composition. ■

Definition (`fixOfO`). For $t \in O$, the element $\mathrm{fixOfO}(t)$ lies in a D-neighbourhood Z when Z is the master or t sees $\{0\}$ and u lies in Z.

Proof. By the element axioms. ■

Theorem (`mem_fixOfO`). Membership in $\mathrm{fixOfO}(t)$ is characterized by D-membership and either master equality or top-like behaviour of t together with membership of u.

Proof. By definition. ■

Theorem (`O_le_iff`). In O, order is determined by extending membership at $\{0\}$.

Proof. By comparison of the two possible neighbourhoods. ■

Theorem (`fixOfO_mono`). The map $t \mapsto \mathrm{fixOfO}(t)$ is monotone in t.

Proof. By the order characterization on O and the membership definition. ■

Theorem (`fixOfO_ne_bot_iff`). For non-bottom u, $\mathrm{fixOfO}(t)$ is not bottom if and only if t lies in $\{0\}$.

Proof. By element extension and the proper-neighbourhood witness for u. ■

Theorem (`mem_toElementMap_check`). The check of an element lies in $Y \subseteq O$ when Y is in O and either Y is the master or the element is not bottom.

Proof. By the element-map characterization and the proper-neighbourhood lemma. ■

Theorem (`check_toElementMap_fixOfO`). For non-bottom u, applying check to $\mathrm{fixOfO}(t)$ returns t.

Proof. By element extension and the non-bottom criterion. ■

Theorem (`mem_toElementMap2_fade`). The binary fade at (t, y) lies in Z when Z is a D-neighbourhood and either Z is the master or t sees $\{0\}$ and y lies in Z.

Proof. By the binary element-map law. ■

Theorem (`toElementMap_ofMap2_pair`). The element map of a curried binary combinator on a pair agrees with the binary element map at the paired arguments.

Proof. By the pairing identities for binary maps. ■

Theorem (`mem_toElementMap_a`). The endomap a sends x into Z when Z is in D and either Z is the master or x is not bottom and u lies in Z.

Proof. By unfolding composition, fade, check, and the pairing lemmas. ■

Theorem (`fixOfO_check_toElementMap`). fixOfO applied to the check of x equals the action of a on x.

Proof. By element extension and the characterization of check at $\{0\}$. ■

Theorem (`toElementMap_a_fixOfO`). For non-bottom u, a fixes every fixOfO(t).

Proof. By element extension and the membership laws. ■

Definition (`fixIso`). For non-bottom u, fixed points of a are order-isomorphic to elements of O via fixOfO and check.

Proof. By the inverse laws, fixed-point equation, and monotonicity on both sides. ■

Theorem (`Otop_ne_Obot`). The top of O is not bottom.

Proof. By membership at $\{0\}$. ■

Theorem (`a_bot`). The endomap a sends bottom to bottom.

Proof. By element extension and master-only outcomes. ■

Theorem (`a_of_ne_bot`). On non-bottom arguments, a returns the anchor u.

Proof. By element extension and the fade–check scheme. ■

Theorem (`isRetraction_a`). For non-bottom u, the map a is a retraction.

Proof. By case analysis on bottom versus non-bottom and the actions above. ■

Theorem (`example84a`). For non-bottom u, a is a retraction and its fixed-point set is order-isomorphic to O.

Proof. By the retraction theorem and the fixed-point isomorphism. ■

Theorem (`check_toElementMap_mem_zero_iff`). Check of an element lies in $\{0\}$ if and only if the element is not bottom.

Proof. By the element-map characterization at $\{0\}$. ■

Theorem (`mem_toElementMap_fade`). On a product $O \times G$, fade at (t, w) lies in Z when Z is in G and either Z is the master or t sees $\{0\}$ and w lies in Z.

Proof. By the specialized fade membership law. ■

4.9.9 Strict retraction

Currying check and fade against evaluation yields the strict combinator of Examples 8.4: a projection on the function space whose fixed points are exactly the strict maps, order-isomorphic to the strict function domain.

Definition (`strictEvalFade`). The strict evaluator applies fade on the codomain after pairing the check of the function argument with the value of the function at that argument.

Proof. By composition on the product of the function space with the domain. ■

Definition (`strictRetraction`). The strict combinator is the curry of the strict evaluator.

Proof. By currying. ■

Theorem (`toApproxMap_strictRetraction_mem`). Applying the strict combinator to a filter function and then to y lies in Z when Z is in the codomain and either Z is the master or y is not bottom and the original function value at y lies in Z.

Proof. By unfolding curry, evaluation, fade, and check. ■

Theorem (`strictRetraction_apply_bot`). The strict image of a function sends bottom to bottom in the codomain.

Proof. By element extension and the membership characterization. ■

Theorem (`isStrict_toApproxMap_of_fixed`). A filter function fixed by the strict combinator is strict.

Proof. By the bottom-action characterization of strictness. ■

Theorem (`strictRetraction_apply_of_ne_bot`). On non-bottom arguments, the strict image agrees with the underlying function value.

Proof. By element extension and the membership equivalence. ■

Theorem (`toApproxMap_toFilter`). Converting a filter to an approximable map and back recovers the original map.

Proof. By the function-space equivalence. ■

Theorem (`toFilter_toApproxMap`). Converting an approximable map to a filter and back recovers the original filter.

Proof. By the function-space equivalence. ■

Theorem (`strictRetraction_fixed_of_isStrict`). The strict combinator fixes the filter of every strict approximable map.

Proof. By elementwise agreement on bottom and non-bottom arguments. ■

Definition (`strictRetractionFixIso`). Fixed points of the strict combinator on filters are order-isomorphic to strict approximable maps.

Proof. By conversion between filters and maps, strictness, and the function-space order equivalence. ■

Theorem (`strictRetraction_le_idMap`). The strict combinator lies below the identity on the function space.

Proof. By comparison of element maps and the non-bottom agreement lemma. ■

Theorem (`toApproxMap_injective`). If two filter functions determine the same approximable map, they are equal.

Proof. By recovery through conversion to filters. ■

Theorem (`isRetraction_strictRetraction`). The strict combinator is a retraction.

Proof. By elementwise idempotence on bottom and non-bottom arguments. ■

Theorem (`example84b_strict`). The strict combinator is a projection whose fixed points are order-isomorphic to the strict function domain.

Proof. By the retraction and identity bounds, and the fixed-point isomorphism composed with the strict-domain equivalence. ■

4.9.10 Smash retraction

Iterating check and fade on both factors of a product yields the smash combinator of Examples 8.4: a projection onto the smash product, identified with the subdomain retraction of the smash subsystem.

Theorem (`pair_bot_bot`). Pairing the bottoms of two systems is the bottom of the product.

Proof. By element extension on product neighbourhoods. ■

Theorem (`prod_bot_fst`). The first component of product bottom is bottom in the first factor.

Proof. By the pairing lemma and projection identities. ■

Theorem (`prod_bot_snd`). The second component of product bottom is bottom in the second factor.

Proof. By the pairing lemma and projection identities. ■

Definition (`smashFadeInner`). The inner smash fade applies product fade after pairing the check of the second component with the identity on the product.

Proof. By composition on the product. ■

Definition (`smashRetraction`). The smash combinator applies product fade after pairing the check of the first component with the inner smash fade.

Proof. By composition on the product. ■

Theorem (`exists_smash_witness`). When both components are non-bottom, each product element lying in a neighbourhood admits a smash neighbourhood contained in that neighbourhood and containing the element.

Proof. By proper-neighbourhood witnesses in each factor and the smash product description of product neighbourhoods. ■

Theorem (`smashFadeInner_mem`). Membership for the inner smash image matches master collapse or non-bottom second component with membership of the original pair.

Proof. By unfolding composition, fade, check, and projections. ■

Theorem (`smashRetraction_mem`). Membership for the smash image matches master collapse or non-bottom first component with inner membership.

Proof. By the fade membership law on the product. ■

Theorem (`smashRetraction_mem_iff`). Membership for the smash image is equivalent to product membership and either master equality or non-bottom status in both factors with membership of the original pair.

Proof. By combining the smash and inner membership characterizations. ■

Theorem (`smashRetraction_le_idMap`). The smash combinator lies below the identity on the product.

Proof. By the membership equivalence and upward closure from the pair itself. ■

Theorem (`smashRetraction_of_eq_bot`). If either component is bottom, the smash image is product bottom.

Proof. By element extension and case analysis on master versus proper behaviour. ■

Theorem (`smashRetraction_of_ne_bot`). When both components are non-bottom, the smash image is the original pair.

Proof. By element extension and the membership equivalence. ■

Theorem (`isRetraction_smashRetraction`). The smash combinator is a retraction.

Proof. By case analysis on bottom components and the idempotence lemmas. ■

Theorem (`smash_subsystem_prod`). The smash product embeds as a subdomain of the product.

Proof. By master coincidence, membership split between master and proper product pieces, and intersection closure. ■

Theorem (`mem_toElementMap_retractionOfSubsystem_smash`). The subdomain retraction of the smash embedding lies in Z when Z is a product neighbourhood and some smash neighbourhood below the element is contained in Z.

Proof. By the general retraction relation and upward closure. ■

Theorem (`smashRetraction_eq_retractionOfSubsystem`). The smash combinator equals the subdomain retraction of the smash embedding.

Proof. By element extension and witness construction in each smash case. ■

Theorem (`example84b_smash`). The smash combinator is a projection whose fixed points are order-isomorphic to the smash product domain.

Proof. By identification with the subdomain retraction and the subdomain projection and isomorphism theorems. ■

4.9.11 Examples 8.4 — check, fade, and smash

EXAMPLES 8.4. If a system D over Δ is not trivial, then the two element system $O = \{\{0\}, \{0,1\}\}$ comes from a retraction on D. Specifically, define a combinator

$$\text{check} : D \to O$$

by the relation

$$X \text{ check } Y \quad \text{iff either } Y = \{0,1\} \text{ or } X \neq \Delta.$$

We see $\text{check}(x) = \bot_O$ iff $x = \bot_D$. We leave to the reader the definition of a combinator:

$$\text{fade} : O \times D \to D,$$

where we have for $t \in |O|$ and $x \in |D|$:

$$\begin{aligned} \text{fade}(t,x) &= \bot_D, \text{ if } t = \bot_O; \\ &= x, \text{ if not.} \end{aligned}$$

Now, take any $u \in |D|$ with $u \neq \bot$, and define

$$a(x) = \text{fade}(\text{check}(x), u).$$

Then a is a retraction (not a projection in general) and the range of a is isomorphic to O.

Another way of using these combinators is to find $(D \to_\bot E)$ as a retraction of $(D \to E)$. Specifically, define a combinator

$$\text{strict} : (D \to E) \to (D \to E)$$

by the equation

$$\mathrm{strict}(f) = \lambda x.\ \mathrm{fade}(\mathrm{check}(x), f(x)),$$

where this time

$$\mathrm{fade} : O \times E \to E\ .$$

The range of strict consists exactly of the strict functions and this time strict is a projection whose range is indeed a domain.

Similarly, we can find a projection on $D \times E$ with a range isomorphic to $D \otimes E$ by the combinator such that:

$$\mathrm{smash}(x, y) = \mathrm{fade}(\mathrm{check}(x), \mathrm{fade}(\mathrm{check}(y), \langle x, y\rangle)),$$

for $x \in |D|$ and $y \in |E|$. □

The formalizations are developed in the fixed neighbourhood, fix of O, strict retraction, and smash retraction peers.

Theorem (`example_84`). On a nontrivial domain D, a chosen non-bottom u yields a retraction whose fixed points are order-isomorphic to the two-element system O; the same check–fade scheme gives a projection on the function space onto the strict maps and a projection on the product onto the smash product, each with range isomorphic to the corresponding constructed domain.

Proof. By the fix-of-O, strict-retraction, and smash-retraction peers. ■

4.9.12 Theorem 8.5 — finitary projection test

THEOREM 8.5. For an approximable mapping $a : E \to E$ the following are equivalent:

(i) a is a finitary projection;

(ii) $a(x) = \{Y \in E \mid \exists X \in x.\, X \subseteq Y \wedge X\ a\ X\}$, for all $x \in |E|$.

Proof: Suppose a satisfies (ii) first. Inasmuch as $X \in x$ and $X \subseteq Y$ always imply $Y \in x$, for all $x \in |E|$, we see $a(x) \subseteq x$ must always hold. Moreover, it is obvious that $X \in x$ and $X\ a\ X$ always imply $X \in a(x)$; therefore, $a(x) \subseteq a(a(x))$ for all $x \in |E|$. This shows that a

is indeed a projection.

Let $D = \{X \in E \mid X\ a\ X\}$, then it is easy to check that $D \mathrel{\triangleleft} E$ and that a is determined from D exactly as in 8.2; thus, the fixed-point set of a is isomorphic to a domain, by what we have already proved. So we have shown (ii) implies (i).

In the converse direction, assume that a is a finitary projection. And let the system D be isomorphic to the fixed-point set of a. We have the situation of Theorem 6.15. There is a projection pair,

$$i : D \to E \quad \text{and} \quad j : E \to D,$$

where the connection with a gives:

$$j \circ i = I_D \quad \text{and} \quad i \circ j = a \subseteq I_E.$$

By 6.15, $D \cong D' \mathrel{\triangleleft} E$, and we want to identify D' in terms of a as follows:

$$D' = \{X \in E \mid X\ a\ X\}.$$

Now from a reading of the proof of 6.15 the neighbourhoods of D' are just those corresponding to the finite elements of D. But any such element is a fixed point of a. We have

$$X \in D' \quad \text{implies} \quad a(\uparrow X) = \uparrow X \quad \text{implies} \quad X\ a\ X.$$

Conversely, if $X\ a\ X$ holds, then $\uparrow X \subseteq a(\uparrow X)$. But a is a projection, so $\uparrow X$ is a fixed point. But $i(j(\uparrow X)) = \uparrow X$ means $j(\uparrow X)$ is a finite element of $|D|$. So $X \in D'$, and we have D' identified as desired.

Finally, if we calculate $a = i \circ j$ by the formulae of 6.12 (with D' for D, of course), we obtain our formula (ii). □

The criterion for being a finitary projection just obtained provides us with a very interesting new combinator.

The development is with the fixed neighbourhood peer.

Theorem (`theorem_85`). An endomap is a finitary projection if and only if its action on every element is given by the membership formula with a self-related neighbourhood witness, and each direction of that equivalence holds separately.

Proof. By the fixed-neighbourhood characterisation of finitary projections. ■

4.9.13 Sub

Scott's sub-combinator on endomaps is the retraction of the fixed-neighbourhood subdomain; its fixed points are exactly the finitary projections, in bijection with subdomains.

Definition (`sub`). The sub-combinator sends an endomap to the retraction of its fixed-neighbourhood subdomain.

Proof. By the subdomain retraction construction. ■

Theorem (`fixedNbhd_retractionOfSubsystem`). The fixed neighbourhood system of a subdomain retraction recovers that subdomain.

Proof. By extensionality on membership, comparing Scott's retraction formula with subdomain membership. ■

Theorem (`sub.rel`). The sub-combinator relates two neighbourhoods exactly when both belong to the ambient system and some fixed neighbourhood of the map mediates between them in Scott's sense.

Proof. By unfolding the fixed-neighbourhood retraction relation. ■

Theorem (`sub.mono`). The sub-combinator is monotone in the endomap.

Proof. By monotonicity of the underlying map on the mediating fixed neighbourhood. ■

Theorem (`sub.retractionOfSubsystem`). Applying sub to a subdomain retraction returns that retraction.

Proof. By the fixed-neighbourhood recovery lemma. ■

Definition (`finitaryProjectionSubsystemEquiv`). Fixed points of sub on endomaps correspond order-isomorphically to subdomains of the ambient domain.

Proof. By pairing fixed-neighbourhood systems with subdomain retractions and verifying inverse laws along the sub identification. ■

Theorem (`fixedNbhd_sub`). The fixed neighbourhood system of sub applied to f equals that of f itself.

Proof. By membership extensionality using the sub relation at witness neighbourhoods. ■

Theorem (`isFinitaryProjection_of_sub_eq_self`). A self-fixed sub-combinator defines a finitary projection.

Proof. By identifying with the subdomain retraction of its fixed neighbourhood system. ■

Theorem (`sub_le`). The sub-combinator lies below the original map.

Proof. By extracting the mediating fixed neighbourhood and applying map monotonicity twice. ■

Theorem (`sub_eq_self_of_isFinitaryProjection`). Every finitary projection is fixed by sub.

Proof. By Scott's membership formula for finitary projections and the defining sub relation. ■

Theorem (`sub_eq_self_iff_isFinitaryProjection`). Self-fixedness under sub is equivalent to being a finitary projection.

Proof. By the two implications above. ■

Theorem (`sub_sub`). Sub applied twice equals sub once.

Proof. By congruence on fixed neighbourhoods using the fixed-neighbourhood identification for sub. ■

Theorem (`isFinitaryProjection_sub`). Sub always yields a finitary projection.

Proof. By idempotence of sub. ■

4.9.14 SubApprox

On the function space, the sub-combinator is realized as a continuous endomap whose fixed points are the finitary projections; it is a finitary projection itself and is computable on effectively given domains.

Definition (`Sub8_6.subFilter`). On function-space elements, apply sub to the approximable map corresponding to the argument.

Proof. By the filter–map correspondence on the function space. ■

Theorem (`Sub8_6.toApproxMap_monotone`). Passing to approximable maps preserves the order on function-space elements.

Proof. By monotonicity of the function-space equivalence. ■

Theorem (`Sub8_6.subFilter_mono`). The sub-filter is monotone on function-space elements.

Proof. By monotonicity of sub on approximable maps. ■

Theorem (`Sub8_6.subFilter_monotone`). The sub-filter is a monotone operator.

Proof. By the pointwise monotonicity lemma. ■

Theorem (`Sub8_6.toApproxMap_rel_iSupDirected`). Directed suprema of elements yield directed suprema of the corresponding approximable maps.

Proof. By the directed-supremum law for function-space maps. ■

Theorem (`Sub8_6.sub_toApproxMap_iSupDirected`). The sub-combinator commutes with directed suprema at the map level.

Proof. By the retraction laws and directedness of the underlying approximable maps. ■

Theorem (`Sub8_6.toApproxMap_toFilter`). Converting filter to map and back recovers the map.

Proof. By the standard equivalence identities. ■

Theorem (`Sub8_6.toApproxMap_subFilter`). The sub-filter's approximable map is sub applied to the argument's map.

Proof. By definition. ■

Theorem (`Sub8_6.toFilter_toApproxMap`). Converting map to filter and back recovers the element.

Proof. By the inverse equivalence law. ■

Theorem (`Sub8_6.toApproxMap_injective`). Equality of approximable maps implies equality of function-space elements.

Proof. By injectivity of the equivalence. ■

Theorem (`Sub8_6.subFilter_iSupDirected`). The sub-filter preserves directed suprema on elements.

Proof. By continuity of the underlying map construction. ■

Theorem (`Sub8_6.continuous_subFilter`). The sub-filter is continuous on the function space.

Proof. By the directed-supremum preservation lemmas. ■

Definition (`subApprox`). The approximable endomap on the function space induced by the continuous sub-filter.

Proof. By the continuous-map constructor. ■

Theorem (`subApprox.toElementMap_eq`). Applying the approximable map to an element equals the sub-filter on that element.

Proof. By the continuous-map element law. ■

Definition (`subApprox.fixIso`). Fixed points of sub on the function space correspond order-isomorphically to fixed points of sub on endomaps of the ground domain.

Proof. By pairing filter and map directions through the sub-filter and sub involution. ■

Theorem (`subApprox.isFinitary`). The sub-combinator on the function space is finitary.

Proof. By transporting finitarity along the fixed-point isomorphism and the subdomain representation of finitary projections. ■

Theorem (`Sub8_6.subApprox_le_idMap`). The function-space sub-combinator lies below the identity.

Proof. By comparing element maps and using that sub lies below the identity on maps. ■

Theorem (`Sub8_6.subFilter_subFilter`). The sub-filter is idempotent on elements.

Proof. By map-side idempotence of sub. ■

Theorem (`Sub8_6.subApprox.toElementMap_eq_comp`). Composing the function-space sub-combinator with itself has the same element action as once.

Proof. By the sub-filter idempotence and composition laws for element maps. ■

Theorem (`Sub8_6.isRetraction_subApprox`). The function-space sub-combinator is a retraction.

Proof. By antisymmetry of the element-map comparison from idempotence. ■

Theorem (`Sub8_6.isProjection_subApprox`). It is a projection.

Proof. By combining retraction with being below the identity. ■

Theorem (`Sub8_6.isFinitaryProjection_subApprox`). It is a finitary projection.

Proof. By packaging projection and finitarity. ■

Theorem (`subApprox_rel_iff`). The raw relation on sets of maps reduces to membership in the target together with sub applied to the principal of the source.

Proof. By unpacking the continuous-map relation. ■

Theorem (`subApprox_rel_Xenum_iff`). On encoded function-space generators, the relation is equivalent to a universal condition over decoded indices expressing sub at presentations.

Proof. By specialization of the relation characterization to enumerations. ■

Theorem (`subStep_recDecidable`). The step predicate governing sub at encoded indices is recursively decidable from primrec inclusion testers.

Proof. By primitive-recursive pairing and conjunction of Decidable inclusion tests. ■

Theorem (`sub_rel_iff_exists_index`). At presentation indices, the sub relation is equivalent to existence of a self-related intermediate neighbourhood.

Proof. By the sub relation and surjectivity of the presentation. ■

Theorem (`sub_leastMap_rel_iff`). For principal elements of encoded maps, sub reduces to an index formulation over least-map codes.

Proof. By the least-map characterization at enumerations. ■

Theorem (`subApprox_isComputable`). Relative to a function-space presentation, the sub-combinator is a computable map.

Proof. By RE characterization of the encoded relation using recursive decidability of sub steps. ■

Theorem (`sub_isComputable_of_isEffectivelyGiven`). On an effectively given domain, some presentation of the function space makes sub computable.

Proof. By assembling a standard function presentation and invoking computability of subApprox. ■

4.9.15 DprimeU

For an enumerable cover of neighbourhoods on a domain, index sets record inclusion among indices; interval presentations in the universal domain yield a subsystem isomorphic to the original domain.

Definition (`idxSet`). At index n, the index set comprises those indices m whose neighbourhood sits inside the nth neighbourhood.

Proof. By the subset relation on the cover. ■

Theorem (`mem_idxSet`). Membership in the index set at n is equivalent to the corresponding inclusion of neighbourhoods.

Proof. By definition. ■

Definition (`Yidx`). The nth encoded interval in the universal domain is obtained by the standard split-and-generate construction applied to the index family over all indices.

Proof. By the interval sequence operator with the chosen split specification. ■

Theorem (`D_mem_e`). Every neighbourhood in the enumerable cover belongs to the ambient domain.

Proof. By the covering hypothesis applied at the defining index. ■

Theorem (`e_subset_master`). Each cover neighbourhood lies below the domain master.

Proof. By the sub-master property on witnessed membership. ■

Theorem (`idxSet_inter_of_inter_eq`). When two cover neighbourhoods intersect in a third, the corresponding index sets intersect in the index set of that third.

Proof. By rewriting intersection of index sets as simultaneous inclusions and applying the hypothesis on set intersections. ■

Theorem (`idxSet_zero_eq_univ`). If every index sits below a fixed index, that index's index set is the full index universe.

Proof. By extensionality using the universal inclusion hypothesis. ■

Theorem (`idxSet_zero`). The index set at zero is universal when zero names the master.

Proof. By the master naming hypothesis and sub-master comparisons. ■

Theorem (`self_mem_idxSet`). Each index belongs to its own index set.

Proof. By reflexivity of inclusion. ■

Theorem (`idxSet_subset_iff`). Inclusion of index sets at i and j is equivalent to inclusion of the corresponding neighbourhoods.

Proof. By the self-membership criterion in one direction and transitivity of inclusion in the other. ■

Theorem (`univ_nonempty_nat`). The set of all natural-number indices is nonempty.

Proof. Zero witnesses. ■

Theorem (`Yidx_empty_or_mem`). Each encoded interval is either empty or a legal neighbourhood of the universal domain.

Proof. By the standard empty-or-membership transfer for interval sequences. ■

Theorem (`Yidx_nonempty`). Each encoded interval is nonempty.

Proof. By transferring nonemptiness from the index set at n with witness n. ■

Theorem (`Yidx_mem`). Every encoded interval belongs to the universal domain.

Proof. By ruling out emptiness. ■

Theorem (`Yidx_subset_master`). Each encoded interval sits below the universal master.

Proof. By the interval-sequence sub-master lemma. ■

Theorem (`Yidx_zero`). The interval at index zero equals the universal master.

Proof. By the zero-index master law for interval sequences and universality of the index set at zero. ■

Theorem (`embed_subset_iff`). Inclusion of cover neighbourhoods at indices i and j matches inclusion of their encoded intervals.

Proof. By the index-set comparison and the subset transfer principle for interval presentations. ■

Theorem (`embed_eq_iff`). Equality of cover neighbourhoods matches equality of encoded intervals.

Proof. By antisymmetry of the subset characterizations. ■

Theorem (`exists_inter_index_of_dmem`). When the domain admits the intersection of two cover sets, some index names both the set intersection and the intersection of the encoded intervals.

Proof. By the covering map on the intersection and the intersection transfer for interval presentations. ■

Definition (`DprimeU`). The subsystem generated by encoded intervals: a set is admitted when it equals some $Yidx$, with the universal master and intersection law inherited via intersection indices.

Proof. By the cover, master, sub-master, and intersection witnesses assembled from embedding and existence lemmas. ■

Theorem (`exists_inter_index_of_nonempty`). Nonempty intersection of encoded intervals yields a common intersection index as above.

Proof. By contrapositive transfer of emptiness to index sets and the domain intersection lemma. ■

Theorem (`DprimeU_subsystem`). The encoded-interval system embeds as a subsystem of the universal domain.

Proof. By master coincidence, membership of generators, and intersection closure from the nonempty-intersection index. ■

Definition (`toD`). From an element of the encoded subsystem, form a domain element by reading membership through cover indices matching encoded intervals.

Proof. By the element axioms using cover, master, intersection, and upward-closure transfer along embeddings. ■

Definition (`toDprimeU`). From a domain element, form an encoded-subsystem element by witnessing encoded intervals from cover indices.

Proof. Dually, using intersection indices from domain intersections. ■

Definition (`domainIso`). The two translations are mutually inverse order isomorphisms on ideal elements.

Proof. By element extension on both sides and the order characterization via embeddings and cover. ■

Theorem (`idxSet_eq_iff`). Equality of index sets matches equality of cover neighbourhoods.

Proof. By antisymmetry of the subset equivalence. ■

Theorem (`idxSet_nonempty`). Every index set is nonempty.

Proof. The index witnesses itself. ■

Theorem (`isomorphic_DprimeU`). The original domain and the encoded-interval subsystem are order-isomorphic.

Proof. By packaging the domain isomorphism. ■

4.9.16 Theorem 8.6 — sub combinator

THEOREM 8.6. For any domain E define

$$\mathrm{sub} : (E \to E) \to (E \to E)$$

by the formula

$$X \ \mathrm{sub}\,(f)\ Z \quad \text{iff} \quad \exists Y \in E.\quad X \subseteq Y \ \ f\ Y \subseteq Z,$$

for all $X, Z \in E$ and all $f : E \to E$. Then the range of sub consists exactly of the finitary projections on E, and moreover sub itself is a finitary projection on $(E \to E)$. If E is effectively given, then sub is computable.

Proof: It is trivial to check that $\mathrm{sub}(f)$ is always approximable. Also, it is obvious from the definition that the correspondence

$$f \mapsto \mathrm{sub}(f)$$

preserves directed unions of f's. Thus, sub is itself approximable. We note that

$$X \subseteq Y \ \ f\ Y \subseteq Z \text{ always implies } X\ f\ Z;$$

hence, $\mathrm{sub}(f) \subseteq f$ holds. Also

$$Y\ f\ Y \text{ always implies } Y\ \mathrm{sub}(f)\ Y,$$

hence, $\mathrm{sub}(f) \subseteq \mathrm{sub}(\mathrm{sub}(f))$ holds. This shows sub to be a projection on $(E \to E)$. The effectiveness of the definition makes it also clear that sub is computable when E has a computable presentation.

Since, sub is a projection, its range is the same as its fixed-point set. If

$$\mathrm{sub}(a) = a,$$

then there is no problem in checking that a satisfies 8.5(ii) *and conversely*. So the range of sub picks out exactly the finitary projections in view of 8.5.

Finally, to prove that sub is a finitary projection of $(E \to E)$, we invoke 6.11 and remark that, in view of 8.2, the fixed point set (range) of sub is in a one-one inclusion-preserving correspondence with the domain $\{D \mid D \triangleleft E\}$. □

These results have almost completely translated the theory of $\triangleleft$-subdomains into λ-calculus via the sub-combinator. One last step will complete the passage, and then we shall be able to return to solving domain equations.

4.9.17 Presented intervals

Finite lists of rational half-open intervals present unions used throughout the universal domain.

Definition (`presentedIntervals`). The union of the half-open intervals given by a list of rational endpoints.

Proof. By union over the list. ■

Definition (`clip`). Clip an endpoint pair to lie within the unit interval by taking the maximum of lower bounds with zero and the minimum of upper bounds with one.

Proof. By the lattice operations on rationals. ■

Definition (`clipGe`). Raise the lower endpoint of a pair to at least a given rational bound.

Proof. By supremum with the bound on the first coordinate. ■

Definition (`clipLt`). Lower the upper endpoint of a pair to at most a given rational bound.

Proof. By infimum with the bound on the second coordinate. ■

Definition (`combineIntervals`). Form every pairwise combined interval by meeting lowers and joining uppers across two lists.

Proof. By flat map and map on endpoint pairs. ■

Theorem (`Ico_diff_Ico`). The set difference of two half-open rational intervals is the union of two half-open pieces described by extrema of the four endpoints.

Proof. By case analysis on order relations among the endpoints. ■

Definition (`diffOneList`). Present the difference of two half-open intervals as a list of at most two interval pieces.

Proof. By the endpoint formulas from the difference lemma. ■

Definition (`diffSingleList`). Subtract one interval from each member of an interval list.

Proof. By flat-mapping the single-interval difference. ■

Definition (`diffAllList`). Subtract a list of intervals from one interval by folding single-list differences.

Proof. By left fold starting from the singleton list of the first interval. ■

Definition (`diffLists`). Present the difference of two unions as the flat union of per-interval differences.

Proof. By flat map over the first list. ■

Theorem (`presentedIntervals.mem`). Membership in a presented union is equivalent to membership in some listed half-open interval.

Proof. By unfolding the union and interval membership. ■

Theorem (`presentedIntervals.nil`). The empty list presents the empty set.

Proof. By the membership characterization. ■

Theorem (`presentedIntervals.cons`). Consing an interval presents the union of that interval with the tail presentation.

Proof. By the membership characterization and disjunction. ■

Theorem (`presentedIntervals.append`). Appending lists presents the union of the two presentations.

Proof. By induction on the first list and the cons lemma. ■

Theorem (`presentedIntervals.congr`). Pointwise list equivalence yields equal presented unions.

Proof. By the membership characterization and bidirectional inclusion. ■

Theorem (`presentedIntervals.inter`). Intersection of two presented unions equals the presentation built by combining interval lists.

Proof. By the membership characterization and the combine-interval construction. ■

Theorem (`presentedIntervals.diffOneList`). The list difference of two intervals presents their set difference.

Proof. By the cons lemmas and the rational interval difference identity. ■

Theorem (`presentedIntervals.diffSingleList`). Subtracting one interval from a presentation presents the corresponding set difference.

Proof. By induction on the list and the one-interval case. ■

Theorem (`presentedIntervals.foldl_diffSingleList`). Folding single-list subtraction through a second list presents subtracting the second union from the first.

Proof. By induction on the subtracted list. ■

Theorem (`presentedIntervals.diffAllList`). The all-list difference of one interval against a union presents the set difference.

Proof. By the fold lemma and empty union on the right. ■

Theorem (`presentedIntervals.diffLists`). The list difference of two presentations presents their set difference.

Proof. By induction on the first list and the all-list case. ■

Theorem (`presentedIntervals.map_clip`). Clipping every interval and presenting the list gives the intersection of the original union with the unit half-open interval.

Proof. By the membership characterization and clip inequalities. ■

Theorem (`presentedIntervals.filter_lt`). Filtering to strict lower bounds does not change the presented union.

Proof. By the membership characterization; strict endpoints are already forced on members. ■

Theorem (`presentedIntervals.map_clipLt`). Clipping uppers to a bound and presenting gives the intersection of the union with the open ray below the bound.

Proof. By the membership characterization. ■

Theorem (`presentedIntervals.map_clipGe`). Clipping lowers to a bound and presenting gives the intersection of the union with the closed ray from the bound upward.

Proof. By the membership characterization. ■

4.9.18 Universal domain U

The neighbourhood system of Scott's universal domain on the rationals in the unit half-open interval.

Definition (`UMaster`). The master neighbourhood is the half-open unit interval of rationals.

Proof. By the standard half-open interval. ■

Theorem (`UMaster_nonempty`). The master neighbourhood is nonempty.

Proof. Zero lies in the unit half-open interval. ■

Definition (`UMem`). A set is a candidate neighbourhood when it is a nonempty presented union of rational intervals contained in the master.

Proof. By conjunction of presentation, nonemptiness, and subset. ■

Theorem (`UMem.sub_master`). Every candidate neighbourhood lies in the master.

Proof. By the defining subset clause. ■

Theorem (`UMem.master_mem`). The master itself is a candidate neighbourhood.

Proof. By the singleton unit presentation and nonemptiness. ■

Theorem (`UMem.inter_mem`). Given candidate neighbourhoods and a nonempty witness inside their intersection, their intersection is again a candidate.

Proof. By combining interval lists and the intersection presentation lemma. ■

Definition (`U`). The neighbourhood system whose memberships are the candidate sets over the master, with the standard intersection law.

Proof. By the neighbourhood-system constructor using the master and intersection lemmas. ■

Theorem (`U.mem_iff_scott`). Membership in the universal system is equivalent to being a nonempty union of rational subintervals with endpoints in the closed unit interval and strict increase along each piece.

Proof. By clipping and filtering presentations in both directions. ■

Theorem (`U.no_minimal`). Every neighbourhood splits into two smaller disjoint nonempty neighbourhoods whose union is the original.

Proof. By bisecting at the midpoint of a witnessing interval using density and clip lemmas. ■

Theorem (`U.union_mem`). The union of two neighbourhoods-or-empty is again empty or a neighbourhood.

Proof. By case split and appending interval lists. ■

Theorem (`U.iUnion_mem`). A nonempty finite union of neighbourhoods-or-empty is a neighbourhood.

Proof. By finset induction using the binary union lemma. ■

Theorem (`U.diff_mem`). The set difference of two neighbourhoods is empty or again a neighbourhood.

Proof. By the list difference presentation of unions. ■

Theorem (`U.diffClosed`). The universal system is closed under difference.

Proof. By the difference membership lemma. ■

Theorem (`U.isPositive`). The universal system is positive.

Proof. By combining interval lists for nonempty intersections. ■

Theorem (`U.noMinimal`). The universal system has no minimal neighbourhoods.

Proof. By the explicit binary split lemma for each member. ■

4.9.19 Split specification

Splittings of neighbourhoods in the universal system, used to refine atoms along a Y-sequence.

Definition (`SplitSpec`). A split operation satisfies the specification when splittings are compatible with emptiness, lie in the universal system, decompose intersections and differences of atom sets, and form a disjoint cover of the ambient neighbourhood.

Proof. By the stated universal quantification over splits. ■

Theorem (`exists_split`). Under the standard empty–neighbourhood correspondence for an atom set and universal ambient, every stage admits a splitting into two universal pieces with the required intersection and difference behaviour.

Proof. By case analysis on whether the atom intersects the next stage set, using no-minimality when both parts are nonempty. ■

Definition (`genAtom`). The generalized atom sequence intersects the master set, at each step keeping or discarding the current stage set according to a boolean stream.

Proof. By primitive recursion on the step index. ■

4.9.20 Atoms of U

Atoms of the universal neighbourhood refine along a boolean stream using a splitting function.

Definition (`atomU`). At stage zero the atom is the master neighbourhood; at each successor, take the first or second split of the current generalized atom against the next stage set.

Proof. By primitive recursion using the split function. ■

Theorem (`atomU_zero`). Every atom stream starts at the master neighbourhood.

Proof. By definition of the recursion base. ■

Definition (`extendTrue`). Extend a finite boolean prefix to an infinite stream that is constantly true afterward.

Proof. By comparison of the index with the prefix length. ■

Definition (`Yseq`). The Y-sequence at length n is the union over all boolean prefixes of the atom one stage later.

Proof. By union over finite boolean functions. ■

Definition (`restrictFin`). Restrict an infinite boolean stream to its values on indices below a fixed bound.

Proof. By evaluation on finite indices. ■

Definition (`splitChoice`). When splitting is legal, choose a witnessing split pair; otherwise return the empty pair.

Proof. By classical choice on the existential split lemma. ■

Theorem (`genAtom_subset`). Generalized atoms always lie inside the master set at each stage.

Proof. By induction on the stage. ■

Theorem (`genAtom_congr`). Agreement of boolean streams below n yields equal generalized atoms at n.

Proof. By induction and the update step. ■

Theorem (`genAtom_forward`). Membership in a generalized atom at n determines exactly which earlier booleans held for the element relative to the stage sets.

Proof. By induction unpacking the intersection steps. ■

Theorem (`genAtom_self`). An element of the master set lies in the generalized atom for the stream that marks exactly the stage sets containing it.

Proof. By induction on the stage using the forward characterization. ■

Theorem (`split_fst_subset`). Under the split specification, the first split piece lies in the ambient neighbourhood.

Proof. By the disjoint cover identity in the specification. ■

Theorem (`split_snd_subset`). Under the split specification, the second split piece lies in the ambient neighbourhood.

Proof. By the disjoint cover identity in the specification. ■

Theorem (`atomU_succ`). The successor atom is given explicitly by the split of the current generalized atom.

Proof. By definition of the recursion step. ■

Theorem (`atomU_congr`). Agreement of streams below n yields equal atoms at n.

Proof. By induction using generalized-atom congruence and the successor formula. ■

Theorem (`atomU_invariant`). At each stage, emptiness of atoms matches generalized atoms, nonempty atoms lie in the universal system, and disagreeing streams yield disjoint atoms.

Proof. By induction using the split specification and disjointness of split pieces. ■

Theorem (`atomU_succ_subset`). Successor atoms sit inside their predecessors.

Proof. By the split subset lemmas and the invariant. ■

Theorem (`extendTrue_agree`). Below the prefix length, extension agrees with the given finite booleans.

Proof. By definition of extension. ■

Theorem (`extendTrue_restrictFin_agree`). Extension of a restriction recovers the original stream on indices below the bound.

Proof. By unfolding extension and restriction. ■

Theorem (`subset_Yseq`). Each atom contributing to a Y-sequence lies inside that sequence.

Proof. By the union defining the Y-sequence. ■

Theorem (`split_fst_eq_inter_Yseq`). The first split piece at stage n equals the current atom intersected with the Y-sequence at n.

Proof. By subset antisymmetry using splits, extension, and the invariant disjointness. ■

Theorem (`atomU_subset_master`). Every atom lies in the master neighbourhood.

Proof. By induction using successor subsets. ■

Theorem (`atomU_succ_eq`). The successor atom is the intersection of the predecessor with either the Y-sequence or the complement of the Y-sequence in the master, according to the boolean at n.

Proof. By case analysis on the boolean and the split identities. ■

Theorem (`atomU_eq_genAtom`). At every stage the atom equals the generalized atom built from Y-sequences and the master.

Proof. By induction using the successor equation. ■

4.9.21 Y-sequence

Y-sequences mediate between stage-wise intersections on a substrate domain and corresponding inclusion structure among universal neighbourhoods.

Theorem (`transfer_dir`). Nonemptiness of generalized atoms with a given finite boolean signature transfers across paired systems when empty stages coincide stepwise.

Proof. By forward membership in generalized atoms and the emptiness witness at the target stage. ■

Theorem (`transfer_empty_iff`). For boolean codes below n, the substrate pattern of membership is nonempty if and only if the corresponding master–Y-sequence pattern is nonempty.

Proof. By applying transfer in both directions through the atom–genAtom correspondence. ■

Theorem (`transfer_subset_iff`). Substrate inclusion between two stages corresponds to master inclusion between the associated Y-sequences.

Proof. By instantiating the empty-set transfer on a two-code witness for subset and difference. ■

Theorem (`transfer_inter_empty_iff`). Two substrate stage-sets meet vacuously if and only if the corresponding Y-sequences are disjoint on the master.

Proof. By the same transfer pattern with two positive codes. ■

Theorem (`transfer_double_subset_iff`). Triple substrate inclusion among two stages and a third corresponds to the analogous triple inclusion among Y-sequences.

Proof. By instantiating transfer on three boolean codes. ■

Theorem (`Yseq_subset_master`). Every Y-sequence lies in the master neighbourhood.

Proof. By union of atoms each contained in the master. ■

Theorem (`Yseq_zero_eq_master`). When the zeroth stage set is the whole substrate, the initial Y-sequence is the master.

Proof. By splitting the master at stage one and Y-sequence inclusion. ■

Theorem (`transfer_inter_eq_iff`). Equality of substrate intersections of three stages corresponds to equality of the three Y-sequence intersections, under stage subsets of the substrate.

Proof. By subset and double-subset transfer lemmas applied to inclusion equivalences. ■

Theorem (`Yseq_empty_or_mem`). Each Y-sequence is either empty or a neighbourhood of the universal system.

Proof. By finite union of universal atoms when nonempty. ■

Theorem (`Yseq_nonempty_of_mem`). Membership at stage n inside the substrate yields a nonempty Y-sequence at n.

Proof. By the decision stream for the witness and nonempty first split piece. ■

Theorem (`splitChoice_isSplitSpec`). The canonical choice split satisfies the split specification.

Proof. By unfolding choice and applying the existential splitting theorem. ■

4.9.22 Definition 8.7 — interval presentation of U

DEFINITION 8.7. Let $\mathbb{Q}$ be the set of rational numbers, and let

$$[0,1) = \{q \in \mathbb{Q} \mid 0 \le q < 1\},$$

and similarly for $[r,s)$ for any $r < s$ in $\mathbb{Q}$. The neighbourhood system $\mathcal{U}$ over $[0,1)$ is the set of all non-empty finite unions of rational intervals $[r,s)$ with $0 \le r < s \le 1$. □

A picture of a typical element of $\mathcal{U}$ could be drawn like this:

Note that any union can be taken as a *disjoint* union of the form

$$\bigcup_{i \le n} [r_{2i}, r_{2i+1})$$

where $0 \le r_0 < r_1 < r_2 < \cdots < r_{2n} < r_{2n+1} \le 1$. (Hint: Any overlapping intervals or abutting intervals can always be combined into one long interval.) It is a most elementary exercise to show that, by virtue

of this representation, the system $\mathcal{U}$ has a computable presentation. (Some isomorphic versions of $\mathcal{U}$ — equally effective — are recorded in the exercises.) Note that $\mathcal{U}$ has no minimal neighbourhoods: every set in $\mathcal{U}$ can be written as the union of two disjoint sets in $\mathcal{U}$. (Hint: Use the density of the ordering of $\mathbb{Q}$.) The significance of $\mathcal{U}$ can now be explained.

The development uses presented intervals, the universal domain $\mathcal{U}$, split specification, atoms of $\mathcal{U}$, and Y-sequences.

Theorem (`definition_87`). The master neighbourhood is the half-open unit interval; membership is exactly nonempty unions of bounded rational subintervals presented by interval lists; the system has no minimal neighbourhoods; some canonical split satisfies the split specification; every atom at stage zero is the master neighbourhood; and each Y-sequence is either empty or a neighbourhood of $\mathcal{U}$.

Proof. The master identity is definition. The membership equivalence is the Scott half-open characterization in terms of clipped interval lists. No minimality is the no-minimal-neighbourhoods theorem. Split specification for the canonical split is proved from existential splitting. The initial atom is the master neighbourhood by definition. Nonempty Y-sequences are finite unions of atoms in $\mathcal{U}$. ■

4.9.23 Fixed neighbourhood effective

Scott's last sentence of Theorem 8.8: the fixed-neighbourhood system of a computable finitary projection is effectively given.

Theorem (`fixedNbhd_isEffectivelyGiven`). If a is a computable approximable endomap on an effectively presented domain, then
$YmidYaY$ is effectively given as a neighbourhood system.

Proof. Via the diagonal fixed-point predicate, primitive-recursive folding on codes, and the D_X presentation machinery. ■

4.9.24 U constructs

Library for $\mathcal{U}+\mathcal{U}, \mathcal{U}\times\mathcal{U}, \mathcal{U}\to\mathcal{U}$: nonemptiness of $\mathcal{U}$-neighbourhoods, effective-presentability of these constructs, their chosen presentations, and the lambda-combinator map used in Definition 8.9.

Theorem (`U_mem_nonempty`). Every neighbourhood in $\mathcal{U}$ is nonempty.
Proof. From the interval presentation of $\mathcal{U}$. ■
Theorem (`funSpaceUU_isEffectivelyGiven`). $\mathcal{U}\to\mathcal{U}$ is effectively given.
Proof. From effective-presentability of $\mathcal{U}$ and the function-space construct. ■
Definition (`funSpaceUUPresentation`). A chosen computable presentation of $\mathcal{U}\to\mathcal{U}$.
Proof. Choose any witness that the function space is effectively given. ■
Definition (`lamComb`). The approximable endomap on $(\mathcal{U}\to\mathcal{U})$ used in the arrow combinator.
Proof. Curry evaluation composed with the indicated product and composition maps. ■
Theorem (`prodUU_isEffectivelyGiven`). $\mathcal{U}\times\mathcal{U}$ is effectively given.
Proof. Product of effectively given $\mathcal{U}$ with itself. ■
Definition (`prodUUPresentation`). A chosen computable presentation of $\mathcal{U}\times\mathcal{U}$.
Proof. Choose any witness that the product is effectively given. ■
Theorem (`sumUU_isEffectivelyGiven`). $\mathcal{U}+\mathcal{U}$ is effectively given.
Proof. Sum of effectively given $\mathcal{U}$ with itself. ■
Definition (`sumUUPresentation`). A chosen computable presentation of $\mathcal{U}+\mathcal{U}$.
Proof. Choose any witness that the sum is effectively given. ■

4.9.25 Theorem 8.8 — universality of U

THEOREM 8.8. The system $\mathcal{U}$ is universal in the sense that, for every countable neighbourhood system $\mathcal{D}$, we have

$$\mathcal{D} \trianglelefteq \mathcal{U}.$$

Moreover, if $\mathcal{D}$ is effectively given, then the projection pair making the embedding can be taken as computable. Indeed there is a correspondence between effectively presented domains and the computable, finitary projections of $\mathcal{U}$.

Proof: ... (Scott's construction via Y_n, effective choice, and finitary fixed neighbourhoods; see peer files for the formal library.) □

The peer development for the diagonal fixed-point predicate, D-side folding, and atom apparatus is imported alongside this packaging file.

Theorem (`theorem_8_8_a`). Every countable neighbourhood system is isomorphic to a subsystem of $\mathcal{U}$.

Proof. By the D'-in-$\mathcal{U}$ construction and the isomorphism/subsystem witnesses already established in the peer library. ■

Theorem (`theorem_8_8`). Every countable neighbourhood system embeds as a subdomain of $\mathcal{U}$ (Scott's $\mathcal{D} \trianglelefteq \mathcal{U}$).

Proof. From `theorem_8_8_a`. ■

Theorem (`theorem_8_8_b`). For an effectively given $\mathcal{D}$, there is an effectively presented subsystem of $\mathcal{U}$, isomorphic to $\mathcal{D}$, with a computable projection pair witnessing the embedding.

Proof. By the coded D'-in-$\mathcal{U}$ construction and its computable injection/projection maps. ■

Theorem (`theorem_8_8_c`). Every computable finitary projection a on $\mathcal{U}$ yields an effectively given fixed-neighbourhood subdomain of $\mathcal{U}$.

Proof. `fixedNbhd_isEffectivelyGiven` for the map's computability, and the standard fixed-neighbourhood subsystem embedding. ■

Theorem (`theorem_8_8_b_strong`). Every effectively presented domain admits a computable projection pair into $\mathcal{U}$ (and back).

Proof. Strengthens `theorem_8_8_b` with an explicit computable retraction pair into $\mathcal{U}$. ■

4.9.31 Definition 8.9 — constructs on projections

DEFINITION 8.9. Let the computable projection pairs $i_+ : \mathcal{U} + \mathcal{U} \to \mathcal{U}$ and $j_+ : \mathcal{U} \to \mathcal{U} + \mathcal{U}$ be fixed. Similarly choose $i_\times, j_\times$ and $i_\to, j_\to$ for $\mathcal{U} \times \mathcal{U}$ and $\mathcal{U} \to \mathcal{U}$. Define:

$$a + b = \mathrm{cond} \circ \langle \mathrm{which}, i_+ \circ \mathrm{in}_0 \circ a \circ \mathrm{out}_0, i_+ \circ \mathrm{in}_1 \circ b \circ \mathrm{out}_1 \rangle \circ j_+ \,;$$

$$a \times b = i_\times \circ \langle a \circ \mathrm{proj}_0, b \circ \mathrm{proj}_1 \rangle \circ j_\times \,;$$

$$a \to b = i_\to \circ (\lambda f.\, b \circ f \circ a) \circ j_\to \,,$$

for all $a, b : \mathcal{U} \to \mathcal{U}$. □

Definition (`iPlus`), Definition (`jPlus`), Definition (`iTimes`), Definition (`jTimes`), Definition (`iArrow`), Definition (`jArrow`). The six computable maps witnessing $\mathcal{U} + \mathcal{U}$, $\mathcal{U} \times \mathcal{U}$, and $\mathcal{U} \to \mathcal{U}$ as subdomains of $\mathcal{U}$.

Proof. From `theorem_8_8_b_strong` on the corresponding $\mathcal{U}$-construct presentations. ■

Theorem (`definition_89`). Scott's six projection-pair equations hold for the chosen i_*, j_*.

Proof. Conjunction of the individual composite-identity and composite-below-identity lemmas for the six maps. ■

4.9.33 Proposition 8.10 — constructs preserve projections

PROPOSITION 8.10. If $a, b : \mathcal{U} \to \mathcal{U}$ are projections, then so are $a + b$, $a \times b$, and $a \to b$. If a and b are finitary, then so are the others; for the fixed-point set of each of them is isomorphic to the corresponding construct applied to the domains determined by a and b.

Proof: … (Scott's sketch via subdomains and D_a, D_b.) □

Theorem (`proposition_810`). Finitary projections are preserved under $+$, $\times$, and $\to$, with the expected isomorphisms to the corresponding subdomain constructs.

Proof. By the combinator peers' finitary-projection witnesses and fixed-point element isomorphisms. ■

Theorem (`proposition_8_10`). Alias of `proposition_810`.

Proof. Reflexivity. ■

EXERCISES

4.9.35 Dedekind cut projection

This peer constructs a projection whose fixed-point order is the real unit interval, using rational initial intervals as neighbourhoods, and proves that this projection is not finitary.

Definition (`R`). The rational-interval neighbourhood system has as neighbourhoods the half-open intervals $[0, r)$ with rational $0 < r \leq 1$, and master neighbourhood $[0, 1)$.

Theorem (`R_mem_iff`). A set is a neighbourhood of the rational-interval system exactly when it is $[0, r)$ for some rational r with $0 < r \leq 1$.

Proof. This is the defining family of neighbourhoods. ■

Theorem (`R_master`). The master neighbourhood is $[0, 1)$.

Proof. This is the chosen master interval. ■

Theorem (`Ico0_inj`). Positive rational endpoints determine their half-open initial intervals uniquely.

Proof. If one endpoint were smaller, that endpoint would belong to the larger interval but not the smaller one. ■

Theorem (`Ico0_inter`). The intersection of $[0, r)$ and $[0, s)$ is $[0, \min(r, s))$.

Proof. Membership requires being below both endpoints. ■

Theorem (`Ico0_le_of_subset`). If $p > 0$ and $[0, p) \subseteq [0, q)$, then $p \leq q$.

Proof. If $q < p$, positivity forced by the inclusion makes q a member of the first interval but not the second. ■

Definition (`aRel`). Two rational initial intervals are related when their endpoints lie in $(0, 1]$ and the first endpoint is strictly smaller than the second, except that the endpoint 1 is also related to itself.

Theorem (`aRel_combine`). If an endpoint is related to each of two endpoints, then it is related to their minimum.

Proof. Two strict inequalities combine into an inequality to the minimum; the exceptional equality case can occur only when all relevant endpoints are 1. ■

Definition (`a`). The relation on rational initial intervals defines an approximable endomap of the rational-interval neighbourhood system.

Theorem (`aRel_iff`). For valid positive endpoints at most 1, the corresponding intervals are related exactly when the first endpoint is smaller than the second or both endpoints equal 1.

Proof. Uniqueness of positive endpoints removes the existential interval representations. ■

Theorem (`a_rel`). The underlying relation of the approximable map is the endpoint relation just defined.

Proof. This is how the map was constructed. ■

Theorem (`Element.ext_U`). Two elements of the rational-interval system are equal if they agree on every interval $[0, r)$.

Proof. Every neighbourhood belonging to either element has this form, so agreement on these intervals gives extensional equality. ■

Definition (`mkElement`). An upward-closed predicate on positive rational endpoints at most 1, containing 1, determines the element whose neighbourhoods are the corresponding intervals $[0, r)$.

Theorem (`mkElement_mem`). A set belongs to the element built from an endpoint predicate exactly when it is $[0, r)$ for some endpoint satisfying that predicate.

Proof. This is the defining membership condition. ■

Theorem (`R_mem_Ico0`). If $[0, s)$ is a neighbourhood, then $0 < s \leq 1$.

Proof. Represent it by a valid endpoint and use uniqueness of positive endpoints. ■

Definition (`cutU`). For a real t, the cut predicate selects rational $r \leq 1$ lying strictly above $1 - t$, together with the endpoint $r = 1$.

Theorem (`cutU_le1`). Every endpoint selected by the cut predicate is at most 1.

Proof. This is part of the predicate. ■

Theorem (`cutU_one`). The endpoint 1 is selected by every cut predicate.

Proof. It is included by the exceptional endpoint clause. ■

Theorem (`cutU_pos`). If $t \leq 1$, every endpoint selected by its cut predicate is positive.

Proof. Then $1 - t \geq 0$; an endpoint strictly above it is positive, while the exceptional endpoint is 1. ■

Theorem (`cutU_up`). The cut predicate is upward closed among rational endpoints at most 1.

Proof. Increasing an endpoint preserves strict inequality above $1 - t$; if the original endpoint is 1, the bounds force the new endpoint also to be 1. ■

Definition (`cutElt`). A real number $t \leq 1$ determines the rational-interval element selected by its cut predicate.

Theorem (`cutElt_mem`). The interval $[0, r)$ belongs to the cut element for t exactly when r satisfies the cut predicate for t.

Proof. The general endpoint construction and uniqueness of positive interval endpoints give the equivalence. ■

Definition (`cutS`). For an element, its endpoint set consists of the real images of rational r for which $[0, r)$ belongs to the element.

Definition (`cutPoint`). The real point represented by an element is one minus the infimum of its endpoint set.

Theorem (`cutS_bddBelow`). Every endpoint set is bounded below by zero.

Proof. Endpoints of neighbourhood intervals are positive. ■

Theorem (`cutPoint_nonneg`). Every represented cut point is nonnegative.

Proof. The endpoint 1 belongs to every element, so the infimum of the endpoint set is at most 1. ■

Theorem (`cutS_nonempty`). Every endpoint set is nonempty.

Proof. It contains the endpoint 1 arising from the master neighbourhood. ■

Theorem (`cutPoint_le_one`). Every represented cut point is at most 1.

Proof. The nonempty endpoint set is bounded below by zero, so its infimum is nonnegative. ■

Theorem (`cutElt_cutPoint`). Every fixed point of the approximable map is the cut element determined by its represented real point.

Proof. Fixedness expresses membership of an interval through a related smaller interval. The defining property of the infimum then identifies membership with lying strictly above the endpoint infimum, with the master endpoint handled separately. ■

Theorem (`cutU_mono`). If $t \leq t'$, every endpoint selected by the cut for t is selected by the cut for t'.

Proof. Increasing t decreases the threshold $1 - t$. ■

Theorem (`le_iff_U`). One rational-interval element lies below another exactly when membership in every interval $[0, r)$ transfers from the first to the second.

Proof. These intervals comprise all neighbourhoods of the system. ■

Theorem (`cutElt_le_iff`). For $t, t' \in [0, 1]$, the cut element for t lies below that for t' exactly when $t \leq t'$.

Proof. Monotonicity of cut predicates gives one direction. If $t > t'$, density of the rationals supplies an endpoint between the two cut thresholds that belongs only to the first cut. ■

Theorem (`cutElt_injective`). On the real unit interval, equal cut elements have equal real parameters.

Proof. Equality gives both element inequalities, and the order characterization gives both inequalities between the parameters. ■

Theorem (`toElementMap_cutElt`). Every cut element with parameter at most 1 is fixed by the approximable map.

Proof. A related smaller endpoint preserves the cut inequality in the forward direction; rational density inserts a related endpoint below any nonterminal selected endpoint in the reverse direction, while endpoint 1 relates to itself. ■

Definition (`fixOrderIso`). The fixed points of the approximable map are order-isomorphic to the real interval $[0, 1]$, by sending a fixed point to its represented cut point.

Theorem (`aRel_le`). Related rational endpoints are ordered by the usual non-strict order.

Proof. Either the first is strictly smaller, or both are 1. ■

Theorem (`isRetraction_a`). The approximable map is idempotent.

Proof. Composing two strict endpoint steps gives one strict step. Conversely, density of the rationals inserts an intermediate endpoint between distinct related endpoints, while the terminal endpoint 1 factors through itself. ■

Theorem (`isProjection_a`). The approximable map is a projection.

Proof. It is a retraction, and every related pair of intervals is ordered by inclusion because their endpoints are ordered. ■

Theorem (`not_isCompactElt_pos`). Under any order isomorphism from the real unit interval to a neighbourhood-system domain, the image of every positive point is not compact.

Proof. The positive point is the supremum of the directed family of smaller nonnegative points, but no member of that family lies above it; an order isomorphism preserves this least-upper-bound obstruction. ■

Theorem (`not_isFinitary_a`). The projection is not finitary.

Proof. If its fixed points formed a finitary domain, every principal compact approximation of the top fixed point would correspond, under the unit-interval isomorphism, to a compact point. No positive point is compact, so all such approximations would be the bottom point; their directed supremum would then make top equal bottom, a contradiction. ■

4.9.36 Exercise 8.11 — retraction on intervals

Let $\mathbb{Q}$ be the set of rational numbers and define a neighbourhood system by the equation

$$R = \{[0, r) \mid r \in \mathbb{Q} \text{ and } 0 < r \leq 1\}.$$

Show that the following defines an approximable map $a : R \to R$:

$$[0, r)\ a\ [0, s) \quad \text{iff} \quad r < s \text{ or } r = s = 1.$$

Show in addition that a is a projection where the fixed-point set of a is in a one-one correspondence with the *real* numbers between 0 and 1 inclusive. (Hint: Recall Dedekind cuts and show $\subseteq$ matches $\leq$.) Conclude that a is *NOT* finitary. (Hint: Aside from $\bot$ there are no finite elements for $\{x \mid x = a(x)\}$.)

The development is with the Dedekind cut projection peer.

Theorem (`example_811`). On the rational interval system, Scott's map is a non-finitary projection.

Proof. By assembling the peer lemmas named in the packaging module. ■

    DedekindCutProjection.not_isFinitary_a⟩
```

4.9.37 Effective isomorphism U and V

This peer completes the effective back-and-forth construction between the computable presentations of Scott's universal domains U and V.

Definition (`effectiveIso812_UV`). The computable presentations of U and V are effectively isomorphic.

Proof. The effective back-and-forth theorem applies because both presentations have computable difference and union operations, positive and difference-closed neighbourhood structures, no minimal non-master neighbourhoods, computable splitting operations, nonempty master neighbourhoods, and compatible distinguished initial elements. ■

4.9.39 Boolean-algebra filters

This peer realizes the countable atomless Boolean algebra through binary-coordinate subsets of the natural numbers, relates its neighbourhood system to the universal domain, and connects Boolean entailment with inclusion of truth sets.

Theorem (`exercise813a`). The universal neighbourhood domain is domain-isomorphic to the domain built from finite binary level sets.

Proof. Use the established effective isomorphism between the two neighbourhood systems and forget the extra effectiveness data. ■

Theorem (`example_813_a`). The universal neighbourhood domain and the binary level-set domain are domain-isomorphic.

Proof. This is the preceding isomorphism. ■

Theorem (`generator_nonempty`). Every binary-coordinate generator is nonempty.

Proof. The number 2^i has its i-th binary digit set. ■

Theorem (`generators_independent`). For any finite set of coordinates and any prescribed Boolean values on them, the intersection choosing each generator or its complement accordingly is nonempty.

Proof. Form the bit mask of precisely those prescribed coordinates whose value is true. Its bits satisfy all the choices. ■

Theorem (`levelSet_compl`). The complement of a binary level set of period 2^k is the level set whose residue mask selects exactly the previously unselected residues.

Proof. A number lies in the complement exactly when the bit for its residue modulo 2^k is absent from the original mask. ■

Theorem (`V.compl_mem`). The complement of a neighbourhood in the binary level-set system is either empty or again a neighbourhood.

Proof. Rewrite the complement as a level set and distinguish whether that level set is empty. ■

Theorem (`testBit_mod_two_pow`). The i-th bit of n modulo 2^k equals the i-th bit of n when $i < k$, and is false otherwise.

Proof. Division by 2^k separates the low k binary digits from all higher digits. ■

Theorem (`affine_eq_biInter`). For a residue $\ell < 2^k$, its congruence class modulo 2^k is the intersection, over the first k coordinates, of the generator or its complement according to the corresponding bit of ℓ.

Proof. Two numbers below 2^k are equal exactly when their first k bits agree, and reduction modulo 2^k retains precisely those bits. ■

Theorem (`generatedBy_affine`). Every congruence class modulo a power of two belongs to the Boolean algebra generated by the binary-coordinate generators.

Proof. Use its finite-intersection description and close the generated family under complements and intersections. ■

Theorem (`generatedBy_biUnion_affine`). A finite union of congruence classes modulo 2^k, all with valid residues, belongs to the generated Boolean algebra.

Proof. Induct over the finite set of residues, using generation of each class and closure under union. ■

Theorem (`generatedBy_levelSet`). Every binary level set belongs to the Boolean algebra generated by the coordinate generators.

Proof. A level set is the finite union of the congruence classes selected by its mask. ■

Theorem (`testBit_mod_two_pow_succ`). Reducing a number modulo 2^{i+1} preserves its i-th bit.

Proof. The coordinate i lies below $i + 1$, so the general reduction formula applies. ■

Theorem (`generator_eq_levelSet`). Each coordinate generator is a level set of period 2^{i+1}, selecting precisely those residues whose i-th bit is one.

Proof. Reduction modulo 2^{i+1} preserves the relevant bit. ■

Theorem (`V.mem_generator`). Every coordinate generator is a neighbourhood of the binary level-set system.

Proof. Express it as a nonempty level set. ■

Theorem (`generatedBy_generator_imp`). Every set in the Boolean algebra generated by the coordinate generators is either empty or a neighbourhood of the binary level-set system.

Proof. Induct through the generation rules. Generators and the whole space are neighbourhoods; finite intersections remain level sets, unions are closed, and complements are empty or neighbourhoods. ■

Theorem (`V.mem_iff_generatedBy`). A set is a neighbourhood of the binary level-set system exactly when it is a nonempty member of the Boolean algebra generated by the coordinate generators.

Proof. Level sets are generated; conversely, the preceding induction says that a nonempty generated set must be a neighbourhood. ■

Definition (`Formula`). A propositional formula is built from countably many variables, falsity, truth, negation, conjunction, and disjunction.

Definition (`evalSet`). The set interpretation sends a variable to its coordinate generator and interprets the Boolean connectives by the corresponding operations on subsets of the natural numbers.

Definition (`evalV`). The valuation interpretation assigns Boolean values to formulas by the usual truth tables.

Definition (`SemanticEquiv`). Two formulas are semantically equivalent when they have the same truth value under every Boolean valuation.

Theorem (`exists_bitsOf_agree`). Given finitely many variables and a Boolean valuation, there is a natural number whose binary digits agree with that valuation on all those variables.

Proof. Take the bit mask of the variables assigned true. ■

Definition (`formulaSetoid`). Semantic equivalence is an equivalence relation on formulas.

Definition (`Lindenbaum`). The Lindenbaum algebra is the quotient of formulas by semantic equivalence.

Theorem (`mem_evalSet_iff`). A natural number belongs to the set interpretation of a formula exactly when the formula is true under the valuation given by that number's binary digits.

Proof. Induction on the formula follows the Boolean operations in the two interpretations. ■

Definition (`vars`). The variables of a formula form the finite set obtained recursively from its variable occurrences.

Theorem (`evalV_eq_of_agree`). Two valuations that agree on every variable of a formula give that formula the same truth value.

Proof. Induction on the formula; compound formulas use agreement on the variables of each constituent. ■

Theorem (`semanticEquiv_iff_evalSet_eq`). Two formulas are semantically equivalent exactly when their set interpretations are equal.

Proof. Semantic equivalence gives pointwise equality on binary valuations. Conversely, realize the finitely many variables of both formulas as bits of one natural number and use invariance under agreement on occurring variables. ■

Definition (`Lindenbaum.toSet`). A semantic-equivalence class is sent to the common set interpretation of its representatives.

Theorem (`Lindenbaum.toSet_mk`). The set assigned to the class of a formula is its set interpretation.

Proof. This is the quotient construction applied to that representative. ■

Definition (`Entails`). A formula entails another when every valuation satisfying the first also satisfies the second.

Theorem (`Lindenbaum.toSet_injective`). The set interpretation of the Lindenbaum algebra is injective.

Proof. Equal set interpretations imply semantic equivalence, so the representing formulas determine the same quotient class. ■

Theorem (`entails_iff_evalSet_subset`). A formula entails another exactly when its set interpretation is contained in that of the other.

Proof. Inclusion immediately handles valuations arising from binary digits. For an arbitrary valuation, realize all variables occurring in either formula by one natural number and transfer both truth values along agreement. ■

Theorem (`example_813_b`). Boolean entailment between formulas is exactly inclusion between their set interpretations.

Proof. This is the preceding entailment characterization. ■

4.9.40 Generated-by filters

This peer isolates the Boolean algebra of subsets generated by the binary-coordinate sets of the natural numbers and records the finite bit-mask calculations used later.

Definition (`GeneratedBy`). A set is generated by a sequence of generators when it can be obtained from individual generators and the whole space by finitely many intersections, unions, and complements.

Definition (`bitmaskOf`). The bit mask of a finite set of natural numbers is the sum of the corresponding powers of two.

Theorem (`testBit_sum_two_pow`). The i-th bit of the sum of distinct powers 2^j, with j ranging over a finite set, is set exactly when i belongs to that set.

Proof. Distinct binary place values give precisely the listed bit indices. ■

Theorem (`testBit_bitmaskOf`). The i-th bit of the bit mask of a finite set is set exactly when i belongs to the set.

Proof. This is the preceding characterization applied to the defining sum. ■

Definition (`generator`). The i-th generator is the set of natural numbers whose i-th binary digit is one.

Theorem (`mem_generator`). A natural number belongs to the i-th generator exactly when its i-th binary digit is one.

Proof. This is immediate from the definition of the generator. ■

4.9.41 Exercise 8.13 — Boolean-algebra filters

(For logicians.) Prove that the universal domain U is isomorphic to the domain of all proper filters of the free Boolean algebra on $\aleph_0$-generators (= the Lindenbaum algebra of propositional calculus). (For topologists.) Connect this

representation of $\mathcal{U}$ with the collection of non-empty open subsets of the product space $2^{\mathbf{N}}$ (= Cantor space).

The development is with the Boolean-algebra filters peer.

Theorem (`example_813`). The Boolean-algebra filter presentation is effectively isomorphic to U.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.42 Closure operator domain

This peer proves that the fixed points of an inflationary retraction form a finitary domain, with compact fixed points obtained by closing principal elements.

Definition (`ClosureOperator`). An approximable endomap is a closure operator when it is a retraction and lies above the identity map.

Definition (`IsCompactFix`). A fixed point is compact among fixed points when, whenever it lies below the directed supremum of a family of fixed points, it already lies below one member of that family.

Definition (`CompactFix`). A compact fixed point is a fixed point equipped with the assertion that it is compact among fixed points.

Definition (`botFix`). The least fixed point of a closure operator is the closure of the least element.

Theorem (`botFix_le`). The least fixed point lies below every fixed point.

Proof. Monotonicity sends the least element below the closure of any fixed point, which equals that fixed point. ■

Theorem (`isCompactFix_botFix`). The least fixed point is compact among fixed points.

Proof. In any nonempty directed family it lies below every member, hence below a chosen member. ■

Definition (`botK`). The bottom compact fixed point is the least fixed point together with its compactness.

Theorem (`le_toElementMap_of_isClosureOperator`). Every element lies below its image under a closure operator.

Proof. The closure operator lies above the identity, and map order is evaluated pointwise on elements. ■

Theorem (`isCompactFix_sup`). If two compact fixed points have a common upper bound, then the closure of their bounded supremum is a compact fixed point.

Proof. Below a directed supremum, each compact point lies below some family member; directedness gives one member above both, and monotonicity of closure places the closed supremum below that fixed member. ■

Theorem (`isCompactFix_toElementMap_principal`). The closure of every principal element is a compact fixed point.

Proof. Inflationarity reduces a bound on its closure to a bound on the principal element; compactness of principal elements chooses one family member, and monotonicity of closure completes the comparison. ■

Definition (`genK`). A basic neighbourhood determines the compact fixed point obtained by closing its principal element.

Definition (`joinCompactFix`). Two compact fixed points below a common fixed point are joined by closing their bounded supremum.

Theorem (`joinCompactFix_le`). The joined compact fixed point remains below the chosen common fixed upper bound.

Proof. The bounded supremum lies below the upper bound, and closure is monotone while the upper bound is fixed. ■

Definition (`upFix`). The upper neighbourhood generated by a compact fixed point consists of all compact fixed points above it.

Theorem (`mem_upFix`). Membership in an upper neighbourhood is exactly domination of its generating compact fixed point.

Proof. This is the defining condition. ■

Theorem (`self_mem_upFix`). A compact fixed point belongs to its own upper neighbourhood.

Proof. The order is reflexive. ■

Theorem (`upFix_antitone`). If one compact fixed point lies below another, the upper neighbourhood of the latter is contained in that of the former.

Proof. This follows by transitivity of the order. ■

Theorem (`upFix_injOn`). Equal upper neighbourhoods have generators with equal underlying fixed points.

Proof. Each generator belongs to its own upper neighbourhood; equality yields both order inequalities, hence antisymmetry. ■

Theorem (`upFix_inter`). For two compact fixed points with a common fixed upper bound, the intersection of their upper neighbourhoods is the upper neighbourhood of their join.

Proof. A compact fixed point lies above both generators exactly when it lies above their bounded supremum and therefore above its closure; the reverse implication uses inflationarity and the inclusion of each generator in the supremum. ■

Theorem (`upFix_subset_upFix_botK`). Every upper neighbourhood is contained in the upper neighbourhood generated by the bottom compact fixed point.

Proof. The bottom fixed point lies below every fixed point. ■

Definition (`domainOfClosure`). The domain of a closure operator is the neighbourhood system whose tokens are compact fixed points and whose basic neighbourhoods are their upper neighbourhoods.

Definition (`confirmedIdx`). For an element of the closure domain, a confirmed index is a compact fixed point whose upper neighbourhood belongs to that element.

Definition (`instNonemptyConfirmedIdx`). Every closure-domain element has a confirmed index.

Proof. Its master neighbourhood is the upper neighbourhood of the bottom compact fixed point. ■

Theorem (`confirmedIdx_directed`). The underlying fixed points of the confirmed indices of an element form a directed family.

Proof. The element confirms the intersection of two confirmed upper neighbourhoods; a basic upper neighbourhood below that intersection provides a confirmed compact fixed point above both generators. ■

Definition (`fromElementFilter`). A closure-domain element determines the directed supremum of the underlying fixed points of all its confirmed indices.

Definition (`genFamily`). For a fixed point and one of its neighbourhoods, the generated fixed point is the closure of the corresponding principal element.

Theorem (`genFamily_directed`). The generated fixed points associated with the neighbourhoods of a fixed point form a directed family.

Proof. Principal elements associated with an element's neighbourhoods form a directed family, and monotonicity of closure preserves the two required inequalities. ■

Definition (`toElementFilter`). A fixed point determines the closure-domain element that confirms exactly those upper neighbourhoods whose compact generators lie below it.

Theorem (`le_of_toElementFilter_le`). If the closure-domain element associated with one fixed point lies below that associated with another, then the first fixed point lies below the second.

Proof. Test each neighbourhood of the first point using the compact closure of its principal element. Equality of generators for equal upper neighbourhoods and inflationarity show that the neighbourhood also belongs to the second point. ■

Theorem (`toElementFilter_fromElementFilter`). Sending a closure-domain element to its fixed point and then back to a filter returns the original element.

Proof. Compactness turns a bound below the directed supremum into a bound below one confirmed index; antitonicity then gives membership. The converse follows from the canonical inclusion of a confirmed index in the supremum. ■

Theorem (`toElementFilter_mono`). The filter assigned to a fixed point is monotone in that fixed point.

Proof. Any compact generator below the smaller fixed point is below the larger one by transitivity. ■

Theorem (`toElementMap_eq_iSupDirected_genFamily`). Every fixed point is the directed supremum of the closures of the principal elements determined by its neighbourhoods.

Proof. Express the underlying element as the directed supremum of its principal approximants, use preservation of directed suprema by the map, and then use fixedness. ■

Theorem (`fromElementFilter_toElementFilter`). Sending a fixed point to its filter and reconstructing a fixed point returns the original fixed point.

Proof. Every confirmed compact generator lies below the fixed point, while the generated principal family is cofinal in the reconstruction and has supremum equal to the fixed point. ■

Definition (`fixSetOrderIso`). The fixed points of a closure operator are order-isomorphic to the elements of its closure domain.

Theorem (`isCompactFix_iff`). A fixed point is compact among fixed points exactly when it is the closure of a principal element arising from some neighbourhood.

Proof. Compactness selects one member from the directed generated family whose supremum is the fixed point, and the reverse inequality follows from monotonicity and fixedness. The converse is compact-

ness of closed principal elements. ■

Theorem (`isFinitary_of_isClosureOperator`). Every closure operator is finitary.

Proof. Its compact fixed points form the closure domain, whose elements are order-isomorphic to all fixed points. ■

Theorem (`example_814`). Compact fixed points of a closure operator are exactly closures of principal elements, and every closure operator is finitary.

Proof. Combine the compact-fixed-point characterization with the finitarity theorem. ■

4.9.43 Exercise 8.14 — closure operators

A retraction $a : D \to D$ is called a *closure operator* iff $I_D \sqsubseteq a$. On a domain like $P\mathbf{N}$, give some examples of closure operators. (Hint: Close up a set of integers under addition. Is this continuous on $P\mathbf{N}$?) Prove in general for any closure $a : D \to D$ that the fixed-point set of a is always a finitary domain. (Hint: Show that the fixed-point set is closed under intersections and directed unions.) What are the finite elements of the fixed-point set?

The development is with the Closure operator domain peer.

Theorem (`example_814`). Every closure operator on an effectively given domain is a finitary projection.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.44 Finitely generated subsystems

This peer constructs, from a finite list of basic neighbourhood indices, the finitely generated subsystem it determines and then a domain whose elements encode all subsystems of the original neighbourhood system.

Definition (`combineSub`). Given a list and two of its sublists, their combination retains exactly those entries of the original list that occur in at least one sublist.

Theorem (`combineSub_sublist`). The combined list is a sublist of the original list.

Proof. It is obtained by filtering the original list. ■

Theorem (`mem_combineSub`). An index belongs to the combined list exactly when it belongs to the original list and to at least one of the two selected sublists.

Proof. This is the membership criterion for the defining filter. ■

Theorem (`interFrom_combineSub_eq`). If both selected lists are sublists of the same list, intersecting the basic neighbourhoods selected by their combination equals the intersection of the two separately generated intersections.

Proof. Membership on either side says that the point lies in the master neighbourhood and in every basic neighbourhood selected by either sublist. ■

Definition (`finGen`). The finite system generated by a list consists of those neighbourhoods of the ambient system that are intersections of the master neighbourhood with the basic neighbourhoods indexed by some sublist.

Theorem (`finGen_mono`). Enlarging the list of generators enlarges its finite generated system.

Proof. Every sublist of the smaller list is also a sublist of the larger one. ■

Theorem (`finGen_sub_mem`). Every member of a finite generated system is an ambient neighbourhood.

Proof. Ambient membership is part of the defining witness. ■

Theorem (`finGen_sub_master`). Every member of a finite generated system is contained in the ambient master neighbourhood.

Proof. Every ambient neighbourhood is contained in the master neighbourhood. ■

Theorem (`master_mem_finGen`). The master neighbourhood belongs to every finite generated system.

Proof. Use the empty sublist, whose generated intersection is the master neighbourhood. ■

Theorem (`principal_mem_finGen`). If an index occurs in the generating list, its basic neighbourhood belongs to the finite generated system.

Proof. Use the singleton sublist containing that index. ■

Definition (`finGenSys`). The finite generated system is made into a neighbourhood system with the ambient master neighbourhood and with the finite intersections generated by sublists as its neighbourhoods.

Theorem (`mem_finGenSys`). Membership in the finite generated neighbourhood system is exactly membership in the corresponding finite generated family.

Proof. This is the definition of its neighbourhood predicate. ■

Theorem (`finGenSys_subsystem`). Every finite generated neighbourhood system is a subsystem of the ambient system.

Proof. Its neighbourhoods are ambient neighbourhoods, and combining sublists witnesses closure under every ambient intersection that exists. ■

Theorem (`interFrom_cons_eq`). The intersection generated by a list beginning with j is the intersection of the j-th basic neighbourhood with the intersection generated by the remaining list.

Proof. Separate the head condition from the conditions indexed by the tail. ■

Theorem (`finGen_le_iff_forall_mem`). For a subsystem of the ambient system, the finite system generated by a list is contained in that subsystem exactly when every basic neighbourhood indexed by the list belongs to the subsystem.

Proof. One direction uses the singleton-generated members. For the converse, induction on the list and subsystem closure under ambient intersections add one generator at a time. ■

Theorem (`finGen_append_le_iff`). The finite system generated by the concatenation of two lists is contained in a subsystem exactly when each of the two separately generated systems is contained in it.

Proof. Apply the generator criterion and split universal membership over concatenation. ■

Definition (`nbhdGen`). The neighbourhood generated by a list is the set of lists whose finite generated systems contain the one generated by the given list.

Theorem (`mem_nbhdGen`). A list belongs to the neighbourhood generated by another list exactly when its finite generated system contains that of the first list.

Proof. This is the defining membership condition. ■

Theorem (`nbhdGen_antitone`). Inclusion of finite generated systems reverses inclusion of their generated neighbourhoods.

Proof. Compose the two inclusions of finite systems. ■

Theorem (`self_mem_nbhdGen`). Every list belongs to the neighbourhood it generates.

Proof. Its finite generated system contains itself. ■

Theorem (`nbhdGen_inter`). The intersection of the neighbourhoods generated by two lists is the neighbourhood generated by their concatenation.

Proof. Membership means containing both finite generated systems, which by the concatenation criterion is equivalent to containing the finite system generated by the concatenated list. ■

Definition (`SubD`). The subsystem domain has finite lists as tokens and takes the generated neighbourhoods as its neighbourhoods; the neighbourhood generated by the empty list is its master neighbourhood.

Theorem (`finGen_eq_of_nbhdGen_eq`). Equal generated neighbourhoods have equal finite generated systems.

Proof. Each generating list belongs to its own neighbourhood, so equality supplies both inclusions between the finite generated systems. ■

Theorem (`nbhdGen_eq_iff`). Two generated neighbourhoods are equal exactly when their finite generated systems are equal.

Proof. The forward implication is the preceding result, and the reverse implication follows directly from the containment definition. ■

Theorem (`mem_SubD`). A set of lists is a neighbourhood of the subsystem domain exactly when it is generated by some finite list.

Proof. This is the neighbourhood predicate of the subsystem domain. ■

Theorem (`SubD_master`). The master neighbourhood of the subsystem domain is generated by the empty list.

Proof. This is its defining master neighbourhood. ■

Theorem (`exists_common_witness`). If an element of the subsystem domain confirms, separately, witnesses that generate every basic neighbourhood indexed by a finite list, then one confirmed list jointly generates all those basic neighbourhoods.

Proof. Induct on the list and concatenate witnesses; filter closure gives confirmation of their intersection, while monotonicity carries the required generators into the concatenation. ■

Theorem (`interFrom_append_eq`). The intersection generated by a concatenated list equals the intersection of the intersections generated by its two parts.

Proof. Membership splits into the conditions indexed by the two component lists. ■

Definition (`ofSubsystem`). A subsystem determines an element of the subsystem domain by confirming a generated neighbourhood exactly when the subsystem contains every indexed basic neighbourhood in its generating list.

Theorem (`mem_ofSubsystem_nbhdGen`). The element associated with a subsystem confirms the neighbourhood generated by a list exactly when the subsystem contains every basic neighbourhood indexed by that list.

Proof. Equality of generated neighbourhoods is converted to equality of finite generated systems, after which the finite-generator criterion applies. ■

Definition (`toSubsystemSys`). An element of the subsystem domain determines a neighbourhood system whose neighbourhoods are members of finite systems generated by lists confirmed by that element.

Theorem (`toSubsystemSys_subsystem`). The neighbourhood system determined by an element of the subsystem domain is a subsystem of the ambient system.

Proof. Its members are ambient neighbourhoods, and two confirmed witnesses can be concatenated to witness closure under ambient intersection. ■

Theorem (`ofSubsystem_toSubsystem`). Passing from an element to its represented subsystem and back returns the original element.

Proof. A confirmed list plainly supplies its indexed generators; conversely, finitely many separate witnesses can be combined into one common confirmed witness and then enlarged to the desired neighbourhood. ■

Theorem (`mem_nbhdGen_iff`). An element confirms the neighbourhood generated by a list exactly when its represented subsystem contains every basic neighbourhood indexed by that list.

Proof. Replace the element by the element reconstructed from its represented subsystem and apply the membership characterization above. ■

Definition (`toSubsystem`). Each element of the subsystem domain is sent to the ambient subsystem it represents.

Theorem (`toSubsystem_ofSubsystem_mem`). Reconstructing a subsystem from its associated element preserves its neighbourhoods exactly.

Proof. A generated witness yields subsystem membership by the finite-generator criterion; conversely, a basic index for the given neighbourhood supplies a singleton witness. ■

Theorem (`toSubsystem_ofSubsystem`). Passing from a subsystem to its associated element and back returns the original subsystem.

Proof. Their neighbourhood predicates agree by the preceding theorem, and their master neighbourhoods are the same. ■

4.9.45 Subsystem domain

This peer gives the subsystem domain an effective presentation, identifies its elements with subsystems, and characterizes which represented subsystems are effectively given.

Definition (`SubDX`). The n-th basic neighbourhood of the effective subsystem domain is the neighbourhood generated by the finite list decoded from n.

Theorem (`SubDX_inter_eq`). The basic neighbourhood indexed by the code for concatenating two decoded lists is the intersection of the two corresponding basic neighbourhoods.

Proof. Concatenation of lists represents intersection of their generated neighbourhoods. ■

Theorem (`SubDX_masterIdx_spec`). The code of the empty list indexes the master neighbourhood of the subsystem domain.

Proof. Decoding the encoded empty list returns the empty list. ■

Theorem (`SubDX_mem`). Every indexed set is a neighbourhood of the subsystem domain.

Proof. It is generated by its decoded list. ■

Theorem (`SubDX_surj`). Every neighbourhood of the subsystem domain has an index.

Proof. Encode a finite list that generates the given neighbourhood. ■

Theorem (`SubD_cons_computable`). It is decidable, uniformly in two indices, whether some indexed neighbourhood is contained in their intersection.

Proof. The code of the concatenated decoded lists always indexes exactly that intersection. ■

Theorem (`consUpd_foldl_idx`). Iterating the consistency-state update along a list produces, in its index component, the successive intersection of the projected entries selected by the binary mask.

Proof. Induction on the list separates the selected and unselected head cases; only a selected head contributes the next intersection. ■

Definition (`idxCharAt`). The characteristic index at a coded pair is the index component obtained by folding the consistency-state transition over the decoded list, starting from the master index.

Theorem (`idxCharAt_eq_idxchain`). The characteristic index equals the canonical index of the intersection generated by the entries selected from the decoded list.

Proof. The fold calculation identifies its index component with the successive intersection defining the canonical index. ■

Theorem (`primrec_idxCharAt`). If the consistency characteristic is primitive recursive, then so is the characteristic-index function.

Proof. Primitive recursion is preserved by the coded fold, pairing, projection, and composition operations used in the definition. ■

Theorem (`mem_finGen_computable`). Membership of an indexed ambient neighbourhood in the finite system generated by a decoded list is uniformly decidable.

Proof. Search the finitely many binary masks for a selected sublist whose intersection is an ambient neighbourhood and has the required canonical index; all constituent tests are decidable. ■

Theorem (`finGen_subset_computable`). Inclusion between the finite systems generated by two decoded lists is uniformly decidable.

Proof. Such inclusion holds exactly when every generator in the first finite list belongs to the second finite system, reducing the question to a bounded finite universal test. ■

Theorem (`SubD_interEq_computable`). Equality of the intersection of two indexed subsystem neighbourhoods with a third indexed neighbourhood is uniformly decidable.

Proof. Convert neighbourhood equality into equality of the associated finite generated systems, express equality as mutual inclusion, and use decidability of inclusion. ■

Definition (`SubDPresentation`). The subsystem domain receives the computable presentation whose indexing decodes finite lists, whose intersection operation concatenates their codes, and whose master index is the code of the empty list.

Definition (`subsystemIso`). Elements of the subsystem domain and subsystems of the ambient domain are order-isomorphic.

Theorem (`primrec_encodeList_singleton`). Encoding a singleton list is a primitive-recursive function of its entry.

Proof. The singleton code is obtained from pairing with the empty-list code followed by successor. ■

Theorem (`subsystemU_computable_iff_index_set_re`). An element of the effective subsystem domain is computable exactly when the set of indices of ambient basic neighbourhoods belonging to its represented subsystem is recursively enumerable.

Proof. Confirmation of a generated neighbourhood is equivalent to membership of all indices in its decoded finite list. Singleton coding gives one direction, and effective finite universal quantification over decoded lists gives the other. ■

Theorem (`subsystemU_element_computable_iff`). An element of the effective subsystem domain is computable exactly when the basic-neighbourhood indices of its represented subsystem form the range of a primitive-recursive function.

Proof. The index set is nonempty because it contains the master index, so the standard range characterization of nonempty recursively enumerable predicates applies. ■

Theorem (`subsystemU_effectivelyGiven_of_isComputableElement`). Every computable element of the universal subsystem domain represents an effectively given subsystem.

Proof. A primitive-recursive enumeration of its basic-neighbourhood index set supplies the required effective presentation. ■

Theorem (`subsystem_isEffectivelyGiven_of_isEffectivelyGiven`). For every effectively given neighbourhood system there is an effectively given neighbourhood system whose elements are order-isomorphic to its subsystems.

Proof. Choose a computable presentation, equip its subsystem domain with the effective presentation above, and use the subsystem order isomorphism. ■

4.9.46 Exercise 8.15 — domain of subsystems

Give a direct proof that the domain $\{X \mid X \triangleleft D\}$ is effectively presented if D is. (Hint: The finite elements of the domain correspond exactly to the finite systems $X \triangleleft D$.) In the case of $D = \mathcal{U}$, show that the computable elements of the domain correspond exactly to the effectively presented domains (up to effective isomorphism).

The development is with the Subsystem domain peer.

Theorem (`example_815`). The domain of subsystems of an effectively given domain is effectively given.

Proof. By assembling the peer lemmas named in the packaging module. ■

`Exercise_8_15.lean`

```
module

```

4.9.47 Fixed-neighbourhood finitary order

This peer identifies the order on finitary projections with the subsystem order on their fixed neighbourhoods and records the effective part of Scott's exercise.

Theorem (`isFinitaryProjection_le_iff_fixedNbhd_subsystem`). For two finitary projections on the same neighbourhood system, the first projection lies below the second exactly when the fixed-neighbourhood system of the first is a subsystem of that of the second.

Proof. Finitary projections are precisely the fixed points of the operation that extracts the projection generated by fixed neighbourhoods. The order isomorphism between these fixed points and subsystems therefore preserves and reflects the two orders. ■

Theorem (`exercise_8_16_assembly`). The order on finitary projections is characterized by inclusion of their fixed-neighbourhood subsystems, and the fixed-neighbourhood system of every computable approximable map on a computably presented domain is effectively given.

Proof. The first assertion is the preceding order characterization; the second is the effective-presentation theorem for fixed neighbourhoods of a computable map. ■

4.9.48 Exercise 8.16 — order of projections

NeighbourhoodSystems/RetractsOfTheUniversalDomain/Exercise_8_16.lean

@import "Exercise_8_16.lean"

EXERCISE 8.16. For finitary projections $a : E \to E$, write

$$D_a = \{X \in E \mid X \sqsubseteq aX\}$$

(cf. 8.5.). Show that for any two such projections $a, b : E \to E$ we have

$$a \sqsubseteq b \quad \text{iff} \quad D_a \lhd D_b.$$

(This fills in the gap at the end of the proof of 8.6.) Also finish off the proof of 8.8 by showing that if E is effectively given and $a : E \to E$ is computable, then D_a is effectively given.

The development is with the Fixed-neighbourhood finitary order peer.

Theorem (`example_816`). Finitary projections on fixed neighbourhoods are ordered as claimed.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.49 Embeddings into U

This peer develops universality for neighbourhood systems and records the principal embeddings of function, product, and sum domains into Scott's universal domain.

Definition (`IsUniversal`). A neighbourhood system is universal when every neighbourhood system with countably many neighbourhoods is isomorphic to a subsystem of it.

Proof. This is the defining universal embedding property. ■

Theorem (`trianglelefteq_of_isomorphic_left`). If a domain is isomorphic to a second domain and the second is isomorphic to a subsystem of a third, then the first is isomorphic to a subsystem of the third.

Proof. Compose the first isomorphism with the isomorphism witnessing the given subsystem representation. ■

Theorem (`trianglelefteq_trans`). Being isomorphic to a subsystem is transitive.

Proof. Turn the two subsystem embeddings into projection pairs, compose those pairs, recover a subsystem representation of the composite, and compose its isomorphism with the original one. ■

Theorem (`U_isUniversal`). Scott's domain U is universal for neighbourhood systems with countably many neighbourhoods.

Proof. Every such system has an isomorphic copy whose neighbourhoods form a subsystem of U. ■

Theorem (`funSpaceUU_trianglelefteq_U`). The function-space domain $[U \to U]$ is isomorphic to a subsystem of U.

Proof. The canonical arrow injection and projection form a projection pair, hence exhibit the function space as a retract and therefore as an isomorphic subsystem. ■

Theorem (`isUniversal_of_isomorphic`). Any domain isomorphic to a universal domain is itself universal.

Proof. The isomorphism makes the original universal domain an isomorphic subsystem of the target; transitivity then transports every universal embedding to the target. ■

Theorem (`V.isUniversal`). The effectively presented domain V is universal.

Proof. The effective isomorphism between U and V is in particular a domain isomorphism, so universality transfers from U. ■

Theorem (`prodUU_trianglelefteq_U`). The product domain $U \times U$ is isomorphic to a subsystem of U.

Proof. The canonical product injection and projection form a projection pair, which yields the required subsystem representation. ■

Theorem (`sumUU_trianglelefteq_U`). The separated sum of two copies of U is isomorphic to a subsystem of U.

Proof. The canonical sum injection and projection form a projection pair, using the nonemptiness of every neighbourhood of U. ■

4.9.50 Embeddings into U (more)

This peer constructs explicit projection pairs for binary products and sums, reducing them to function spaces and to products involving the three-element truth domain.

Definition (`funToPair`). A function from the truth domain to E determines a pair of elements of E by evaluation at truth and falsity.

Proof. Pair the two evaluation maps obtained by adjoining the constant true and false arguments. ■

Definition (`sumToProdT`). An element of the separated sum $E + E$ determines a triple consisting of its truth-valued tag and its two possible component projections.

Proof. Pair the tag map with the pair of the left and right output maps. ■

Definition (`swapProdT`). The product $(E \times E) \times T$ maps to $T \times (E \times E)$ by exchanging its two factors.

Proof. Pair the second projection with the first projection. ■

Definition (`pairToFun`). A pair (x, y) determines the truth-indexed function that returns x at truth, y at falsity, and the least element at the indeterminate truth value.

Proof. Curry the conditional map after exchanging the truth value and the pair. ■

Theorem (`TD_bot_eq_botElt`). The least element of the truth domain is its indeterminate truth element.

Proof. Each is below the other: one by leastness and the other by the defining least-element property of the indeterminate truth value. ■

Theorem (`TD_trichotomy`). Every element of the truth domain is either indeterminate, true, or false.

Proof. This is the element classification for the neighbourhood system generated by two tokens. ■

Theorem (`funSpace_dom_trianglelefteq`). If A is isomorphic to a subsystem of B, then $[A \to C]$ is isomorphic to a subsystem of $[B \to C]$.

Proof. A projection pair from A to B induces, by contravariance in the argument, a projection pair between the two function spaces; the exponential composition and monotonicity laws verify its equations. ■

Theorem (`outMap0_comp_inMap1`). Projecting the left component after injecting a right-hand element into a separated sum gives the constant least element of the left domain.

Proof. A right injection has no left information beyond the master neighbourhood, so its left output is exactly the least element. ■

Theorem (`outMap1_comp_inMap0`). Projecting the right component after injecting a left-hand element into a separated sum gives the constant least element of the right domain.

Proof. A left injection has no right information beyond the master neighbourhood, so its right output is exactly the least element. ■

Theorem (`pair_bot`). Pairing the least elements of two neighbourhood domains gives the least element of their product.

Proof. Every neighbourhood in the pair is forced to be the product master neighbourhood, while leastness supplies the converse order. ■

Theorem (`prod_left_trianglelefteq`). If A is isomorphic to a subsystem of B, then $A \times C$ is isomorphic to a subsystem of $B \times C$.

Proof. Apply the projection pair for A and B to the first coordinate and leave the second coordinate fixed; the product order verifies the retraction and approximation laws coordinatewise. ■

Theorem (`prod_right_trianglelefteq`). If A is isomorphic to a subsystem of B, then $C \times A$ is isomorphic to a subsystem of $C \times B$.

Proof. Commute both products, use preservation in the left coordinate, and compose the resulting subsystem embeddings. ■

Theorem (`toElementMap_bot_le`). If an approximable map relates the source master neighbourhood only to the target master neighbourhood, then the image of the source least element lies below the target least element.

Proof. Membership in the image of the least element reduces to a relation from the source master neighbourhood, which by hypothesis forces the target master neighbourhood. ■

Theorem (`outMap0_bot_le`). The left output of the least element of a separated sum lies below the least element of the left summand.

Proof. The left part of the sum master neighbourhood is the left master neighbourhood, so the preceding least-image criterion applies. ■

Theorem (`outMap1_bot_le`). The right output of the least element of a separated sum lies below the least element of the right summand.

Proof. The right part of the sum master neighbourhood is the right master neighbourhood, so the least-image criterion applies. ■

Theorem (`toElementMap_funToPair`). On elements, the map from truth-indexed functions to pairs sends φ to $(\varphi(\mathsf{true}), \varphi(\mathsf{false}))$.

Proof. Evaluate the two components of the defining paired map. ■

Theorem (`toElementMap_sumToProdT`). On elements, the sum encoding sends w to the pair formed by its tag and the pair of its left and right outputs.

Proof. This follows directly from the element action of paired maps. ■

Theorem (`condSum_comp_sumToProdT`). Decoding the tag-and-components representation of a separated-sum element returns that element.

Proof. The conditional reconstruction theorem selects the component designated by the tag of the original sum element. ■

Theorem (`toElementMap_swapProdT`). The factor-exchange map sends $((x, y), t)$ to $(t, (x, y))$.

Proof. Compute the two product projections of the input pair. ■

Theorem (`toApproxMap_pairToFun`). Applying the truth-indexed function represented by (x, y) to t is the conditional value determined by $(t, (x, y))$.

Proof. Uncurrying the definition reduces evaluation to the conditional map after factor exchange. ■

Theorem (`funToPair_comp_pairToFun`). Encoding a pair as a truth-indexed function and then evaluating it at truth and falsity returns the original pair.

Proof. The conditional laws at truth and falsity recover the first and second coordinates respectively. ■

Theorem (`pairToFun_comp_funToPair_le`). Reconstructing a truth-indexed function from its values at truth and falsity gives a function below the original one.

Proof. By trichotomy of truth values, the reconstructed function agrees at truth and falsity, while at the indeterminate value it yields the least element. ■

Theorem (`prod_trianglelefteq_funSpace_TD`). The product $E \times E$ is isomorphic to a subsystem of the function space $[T \to E]$.

Proof. The pair-to-function and function-to-pair maps satisfy the retraction equation and the required approximation inequality. ■

Theorem (`prod_trianglelefteq_of`). If the truth domain embeds as an isomorphic subsystem of E, and $[E \to E]$ does likewise, then $E \times E$ is isomorphic to a subsystem of E.

Proof. Embed the product into $[T \to E]$, enlarge the function-space argument from T to E, and then use the assumed function-space embedding. ■

Theorem (`which_bot_le`). The tag of the least separated-sum element lies below the indeterminate truth value.

Proof. The tag map sends the sum master neighbourhood only to the truth master neighbourhood, so the least-image criterion applies. ■

Theorem (`which_inMap0_le_trueElt`). The tag of an injected left-hand element lies below truth.

Proof. Any truth neighbourhood appearing in that tag is either the master or the true token; a false token would force an impossible inclusion of a left injection into a right injection. ■

Theorem (`which_inMap1_le_falseElt`). The tag of an injected right-hand element lies below falsity.

Proof. Any truth neighbourhood appearing in that tag is either the master or the false token; a true token would force an impossible inclusion of a right injection into a left injection. ■

Theorem (`sumToProdT_comp_condSum_le`). Encoding after conditionally decoding a tag and two candidate components gives an approximation below the original triple.

Proof. Split on the three truth values. At the indeterminate value all outputs are least; at truth the left component is recovered and the right is least; at falsity the right component is recovered and the left is least. ■

Theorem (`sum_trianglelefteq_prodT`). The separated sum $E+E$ is isomorphic to a subsystem of $T \times (E \times E)$.

Proof. The sum encoding and conditional decoding form a projection pair by the decoding identity and encoding approximation. ■

Theorem (`sum_trianglelefteq_of`). If the truth domain and the self-function-space of E are each isomorphic to subsystems of E, then the separated sum $E + E$ is isomorphic to a subsystem of E.

Proof. First embed the sum into $T \times (E \times E)$, replace T and $E \times E$ by their embeddings into E, and compose the resulting product embeddings. ■

4.9.51 Projection pairs

This peer isolates projection pairs, the embedding–projection data used to represent one neighbourhood domain as a retract of another.

Definition (`ProjPair`). A projection pair from D to E consists of an injection $i : D \to E$ and a projection $j : E \to D$ such that ji is the identity on D and ij lies below the identity on E.

Proof. These two equations are precisely the retraction and approximation laws for an embedding–projection pair. ■

Definition (`ProjPair.comp`). Projection pairs from D to E and from E to F compose to a projection pair from D to F.

Proof. Compose the injections in the forward order and the projections in the reverse order; associativity, the two retraction laws, and monotonicity give the required identities and inequality. ■

Definition (`ProjPair.ofIso`). Every domain isomorphism determines a projection pair whose injection is the isomorphism and whose projection is its inverse.

Proof. The inverse laws make both composites identities, and equality in particular gives the required approximation inequality. ■

Definition (`ProjPair.ofSubsystem`). Every subsystem inclusion determines a projection pair from the subsystem to its ambient neighbourhood system.

Proof. Use the canonical subsystem injection and projection; their retraction and approximation laws are part of the subsystem construction. ■

4.9.52 Exercise 8.17 — explicit embeddings into U

NeighbourhoodSystems/RetractsOfTheUniversalDomain/ProjPair.lean

@import “ProjPair.lean”

NeighbourhoodSystems/RetractsOfTheUniversalDomain/Exercise_8_17.lean

@import “Exercise_8_17.lean” **EXERCISE 8.17.** Find explicitly (if possible) the projection pairs for $\mathcal{U}+\mathcal{U}$, $\mathcal{U}\times\mathcal{U}$, and $\mathcal{U}\to\mathcal{U}$ needed for 8.9. Are any of these domains isomorphic with $\mathcal{U}$? (The author does not know a really good construction for $\mathcal{U}\to\mathcal{U}$.) Find a universal domain $V\neq\mathcal{U}$.

The development is with the Embeddings into U peer.

Theorem (`example_817`). V is universal; product, sum, and function-space copies of U retract into U.

Proof. By assembling the peer lemmas named in the packaging module. ■

Exercise_8_17.lean

```
module

public import DomainTheory.NeighbourhoodSystems.RetractsOfTheUniversalDomain.

    IsUniversal.{0} V ∧
      (prod U U ? U) ∧
      (sum U U U_mem_nonempty U_mem_nonempty ? U) ∧
      (funSpace U U ? U) :=
  ⟨V.isUniversal, prodUU_trianglelefteq_U, sumUU_trianglelefteq_U,
    funSpaceUU_trianglelefteq_U⟩
```

4.9.53 Projection combinators

This peer assembles the closure properties of projections on the universal domain under the sum, product, and function-space combinators.

Theorem (`exercise_8_18_assembly`). If a and b are projections on U, then their sum, product, and arrow combinators are projections; if a and b are also finitary, all three resulting projections are finitary.

Proof. The projection-closure theorem supplies the three projection laws, and the finitary-closure theorem supplies the corresponding finiteness properties. ■

Theorem (`example_818`). For arbitrary projections a and b on U, the sum, product, and arrow constructions preserve projectionhood, and preserve finitariness whenever both inputs are finitary.

Proof. This is the universally quantified form of the preceding assembly theorem. ■

4.9.55 Sum and product retracts

This peer develops elementary embeddings and projections for sums, products, and function spaces, and assembles the hypotheses under which binary sums and products retract into a universal ambient domain.

Theorem (`exercise_8_19_assembly`). Let E be a neighbourhood system whose neighbourhoods are nonempty. If the truth-value domain and the self-function space $[E \to E]$ are retracts of E, then both $E + E$ and $E \times E$ are retracts of E.

Proof. Apply the sum construction to the truth-value and function-space retractions, and the product construction to the same two hypotheses. ■

Theorem (`example_819`). The preceding simultaneous sum-and-product assertion holds uniformly; moreover, its product and sum conclusions each hold separately under their respective stated hypotheses.

Proof. Combine the general product and sum retraction theorems, then take each component of the conjunction. ■

Definition (`constFunMap`). For neighbourhood systems A and B, the constant-function map sends an element b of B to the element of $[A \to B]$ having constant value b.

Proof. Curry the projection $B \times A \to B$. ■

Definition (`embedFst`). The first-factor embedding $A \to A \times B$ sends a to $(a, \bot)$.

Proof. Pair the identity on A with the constant bottom map into B. ■

Definition (`embedSnd`). The second-factor embedding $B \to A \times B$ sends b to $(\bot, b)$.

Proof. Pair the constant bottom map into A with the identity on B. ■

Definition (`evalBotMap`). Evaluation at bottom sends a function $f : A \to B$ to $f(\bot)$.

Proof. Pair a function with the constant bottom argument and apply evaluation. ■

Theorem (`toApproxMap_constFunMap`). Applying the constant function determined by b to any argument a yields b.

Proof. Uncurry the defining projection; its first coordinate is b, independently of a. ■

Theorem (`embedFst_comp_proj0_le`). Replacing the second coordinate of a pair by bottom lies below the original pair.

Proof. The first coordinates agree, and bottom is below the original second coordinate. ■

Theorem (`embedFst_ne_embedSnd_of_ne_bot`). If x is not bottom in D, then the two embeddings $D \to D \times D$, $y \mapsto (y, \bot)$ and $y \mapsto (\bot, y)$, are distinct.

Proof. Equality of the maps would give equality of their values at x; taking first coordinates would force $x = \bot$. ■

Theorem (`embedSnd_comp_proj1_le`). Replacing the first coordinate of a pair by bottom lies below the original pair.

Proof. Bottom is below the original first coordinate, and the second coordinates agree. ■

Theorem (`proj0_comp_embedFst`). First projection after first-factor embedding is the identity on A.

Proof. The first coordinate of $(a, \bot)$ is a. ■

Theorem (`proj1_comp_embedSnd`). Second projection after second-factor embedding is the identity on B.

Proof. The second coordinate of $(\bot, b)$ is b. ■

Theorem (`toElementMap_evalBotMap`). On elements of the function-space domain, evaluation at bottom is ordinary application to the bottom element of the argument domain.

Proof. Expand evaluation on the pair consisting of the function and the constant bottom argument. ■

Theorem (`constFunMap_comp_evalBotMap_le`). Sending a function f to the constant function with value $f(\bot)$ lies below f.

Proof. Monotonicity of f gives $f(\bot) \leq f(a)$ for every argument a, which is exactly the pointwise order on functions. ■

Theorem (`evalBotMap_comp_constFunMap`). Evaluating a constant function at bottom recovers its constant value.

Proof. Constant functions have the same value at every argument, hence in particular at bottom. ■

Theorem (`trianglelefteq_funSpace_const`). The codomain B is a retract of $[A \to B]$.

Proof. Use constant functions as the embedding and evaluation at bottom as the projection. Their projection–embedding composite is the identity, and the reverse composite lies below the identity. ■

Theorem (`D_trianglelefteq_funSpace`). Every neighbourhood system D is a retract of its self-function space $[D \to D]$.

Proof. Specialize the constant-function retraction to $A = B = D$. ■

Theorem (`trianglelefteq_prod_fst`). The first factor A is a retract of $A \times B$.

Proof. Embed a as $(a, \bot)$ and project to the first coordinate. Projection after embedding is the identity, while the reverse composite lies below the product identity. ■

Theorem (`D_trianglelefteq_prod`). Every neighbourhood system D is a retract of $D \times D$.

Proof. Specialize the first-factor product retraction to $A = B = D$. ■

```

4.9.57 Diagonal retracts

This peer records the two canonical diagonal retractions: every neighbourhood system is a retract of both its self-product and its self-function space.

Theorem (`exercise_8_20_assembly`). For every neighbourhood system D, the domain D is a retract of $D \times D$, and it is also a retract of the function-space domain $[D \to D]$.

Proof. Use the first-coordinate embedding for the product and the constant-function embedding for the function space. ■

Theorem (`example_820`). The conjunction of the preceding two retraction assertions holds uniformly for every neighbourhood system; in particular, each assertion also holds separately.

Proof. Combine the uniform product and function-space retractions, and obtain the two remaining conjuncts by projection. ■

Theorem (`trianglelefteq_prod_snd`). For neighbourhood systems A and B, the second factor B is a retract of $A \times B$.

Proof. Embed b as $(\bot, b)$ and project to the second coordinate. Projection after embedding is the identity, while embedding after projection lies below the identity on the product. ■

@import “Exercise_8_20.lean”

EXERCISE 8.20. For any system we know $D \trianglelefteq D + D$, but what about

$$D \trianglelefteq D \times D \quad \text{and} \quad D \trianglelefteq D \to D\,?$$

Would these projections be computable if D is effectively given? Are there more than one projection pair in each case?

The development is with the Diagonal retracts peer.

Theorem (`example_820`). A domain retracts into its diagonal product and function-space copies.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.59 A-sharp on lists

This peer constructs the sharp operation on endomaps of the universal domain. It develops functoriality of the sharp domain, transports it through a universal embedding–projection pair, and proves the algebraic and computability facts needed later.

Definition (`aSharpInner`). For an endomap a of the universal domain, its inner sharp map is the structural fold on the sharp domain that applies a at leaves and preserves binary pairing.

Proof. Use the sharp-domain recursor with leaf action given by inclusion after a, and node action given by sharp pairing. ■

Definition (`dsharpMap`). A map $f : D_1 \to D_0$ induces a map $D_1^\sharp \to D_0^\sharp$ that applies f to every leaf and preserves the binary-tree structure.

Proof. Define the induced map by structural recursion, using sharp inclusion at leaves and sharp pairing at nodes. ■

Theorem (`dsharpMap_eq`). The induced sharp map is exactly the structural fold with leaf action given by inclusion after the original map and node action given by sharp pairing.

Proof. This is the defining equation of the induced map. ■

Theorem (`dsharpMap_self_eq_aSharpInner`). On the universal domain, the induced sharp map of an endomap a is its inner sharp map.

Proof. Both constructions use the same leaf and pairing operations, so their definitions coincide. ■

Theorem (`grel_inSharp_pairSharp_imp_idMap_rel`). Any relation generated by sharp inclusion at leaves and sharp pairing at nodes relates two valid sharp neighbourhoods W, Z with $W \subseteq Z$.

Proof. Induct on the generated relation. The empty and leaf cases are immediate; in the node case combine the two inductive inclusions coordinatewise and then use the inclusion supplied by the pairing relation. ■

Definition (`iSharp`). Choose the embedding of the sharp universal domain into the universal domain supplied by universality.

Proof. The sharp domain has an effective countable presentation, so the strong universal embedding theorem supplies such a map. ■

Definition (`ISharpComb`). For an endomap a, the forward sharp combinator embeds the sharp domain of the fixed neighbourhood subsystem of a into the universal domain.

Proof. First apply the sharp map induced by the subsystem inclusion, then apply the chosen universal embedding. ■

Theorem (`idMap_rel_imp_grel_inSharp_pairSharp`). If W and Z are valid sharp neighbourhoods and $W \subseteq Z$, then the identity relation is generated from sharp inclusion and sharp pairing.

Proof. Induct on the construction of W. The empty case forces Z to be empty, the leaf case is a generated leaf relation, and the pair case is assembled from the two induction hypotheses and the pairing witness. ■

Theorem (`gMap_inSharp_pairSharp_eq_idMap`). Structural recursion with sharp inclusion at leaves and sharp pairing at nodes is the identity map on $D^\sharp$.

Proof. The two preceding implications show that its relation is equivalent to the identity relation on every pair of neighbourhoods. ■

Theorem (`dsharpMap_id`). The sharp map induced by the identity on D is the identity on $D^\sharp$.

Proof. Its structural fold has sharp inclusion as leaf action and sharp pairing as node action, hence is the identity by the preceding theorem. ■

Theorem (`inSharp_principal`). Sharp inclusion sends the principal element generated by a neighbourhood X to the principal sharp element generated by the corresponding leaf.

Proof. A sharp neighbourhood lies in the image exactly when it is above that leaf, which is the defining membership condition for the principal sharp element. ■

Definition (`jSharp`). Choose the projection from the universal domain onto the sharp universal domain supplied with the universal embedding.

Proof. The strong universal embedding theorem supplies a projection paired with the chosen embedding. ■

Definition (`JSharpComb`). For an endomap a, the backward sharp combinator maps the universal domain into the sharp domain of the fixed neighbourhood subsystem of a.

Proof. Apply the chosen universal projection, then the sharp map induced by the subsystem projection. ■

Definition (`aSharp`). The sharp transform of an endomap a is obtained by projecting into the sharp universal domain, applying the inner sharp map of a, and embedding back into the universal domain.

Proof. Compose the chosen projection, the structural sharp action of a, and the chosen embedding. ■

Theorem (`aSharp.eq`). The sharp transform of a is the composite of the chosen projection, its inner sharp map, and the chosen embedding.

Proof. This is the defining equation of the sharp transform. ■

Theorem (`jSharp_comp_iSharp`). Projecting after embedding the sharp universal domain is the identity.

Proof. This is the left-inverse equation of the chosen universal embedding–projection pair. ■

Theorem (`pair_principal_eq_principal_prodNbhd`). The pair of two principal elements is the principal product element generated by the corresponding product neighbourhood.

Proof. Membership on either side says that a product neighbourhood lies above coordinate neighbourhoods lying above the two generators; the coordinatewise characterization of product inclusion makes these conditions equivalent. ■

Theorem (`pairSharp_principal`). Sharp pairing of principal sharp elements generated by P and Q is the principal sharp element generated by the tree node (P, Q).

Proof. Rewrite the pair as the principal product element and compare membership using the defining relation of sharp pairing. Both sides say exactly that a sharp neighbourhood lies above the paired generator. ■

Theorem (`gMap_eq_of_satisfies`). A strict map out of $D^\sharp$ is uniquely determined by its values on sharp leaves and sharp pairs. If those values agree with prescribed leaf and node operations, the map equals the structural fold generated by those operations.

Proof. Induct on sharp neighbourhoods. Strictness handles the empty constructor, the leaf equation handles leaves, and the pair equation together with the two induction hypotheses handles nodes; extensionality then identifies the maps. ■

Theorem (`dsharpMap_comp`). Sharp lifting preserves composition: the lift of $f' \circ f$ is the composite of the lift of f with the lift of f'.

Proof. The composite is strict, acts on leaves by $f' \circ f$, and preserves sharp pairing. The uniqueness principle for structural folds therefore identifies it with the lift of the composite. ■

Theorem (`ISharpComb_comp_JSharpComb`). If a is a finitary projection, composing the backward sharp combinator with the forward one in the universal domain gives the sharp transform of a.

Proof. Functoriality combines the lifted subsystem projection and inclusion into the lift of a; on the fixed subsystem their composite represents a, and this lift is the inner sharp action used in the sharp transform. ■

Theorem (`JSharpComb_comp_ISharpComb`). For every a, composing the forward sharp combinator with the backward one on the sharp fixed subsystem is the identity.

Proof. Cancel the chosen universal embedding–projection pair, use functoriality of sharp lifting, and use that subsystem projection after inclusion is the identity. ■

Definition (`dsharp_fixedNbhd_elementIso`). For a finitary projection a, the element poset of the sharp fixed neighbourhood system of a is order-isomorphic to the fixed-point poset of the sharp transform of a.

Proof. The two sharp combinators form a mutually inverse projection pair, so their element maps restrict to the required order isomorphism. ■

Theorem (`gMap_selfComp_eq_of_isRetraction`). If $a : D \to D$ is idempotent, then the structural sharp map applying a at leaves and preserving pairs is also idempotent.

Proof. Apply the uniqueness principle for structural folds to its self-composite. At leaves, two applications reduce to one by idempotence of a; at pairs, both applications preserve the same binary structure. ■

Theorem (`GRel.mono_uv`). The relation generated from leaf operation u and node operation v is monotone in both operations: enlarging u and v preserves every generated relation.

Proof. Induct on the generation of the relation. The empty case is unchanged, while the leaf and node cases use the corresponding assumed inequalities and the induction hypotheses. ■

Theorem (`aSharpInner_eq`). The inner sharp action of a is the structural fold that applies inclusion after a at leaves and sharp pairing at nodes.

Proof. This is its defining equation. ■

Theorem (`aSharpInner_idem_of_isRetraction`). If a is idempotent, then its inner sharp action is idempotent.

Proof. Apply the idempotence theorem for structural sharp maps to a. ■

Theorem (`gMap_mono`). Structural sharp recursion is monotone in both its leaf operation and its node operation.

Proof. Every relation generated from the smaller operations remains generated from the larger ones by monotonicity of the inductively generated relation. ■

Theorem (`iSharp_comp_jSharp_le`). Embedding after projecting the universal domain through its sharp retract lies below the identity.

Proof. This is the order inequality of the chosen universal embedding–projection pair. ■

Theorem (`dsharpU_trianglelefteq_U`). The sharp universal domain is a retract of the universal domain.

Proof. The chosen embedding and projection have identity projection–embedding composite, while their reverse composite lies below the identity. ■

Theorem (`iSharp_isComputableMap`). The chosen embedding of the sharp universal domain into the universal domain is computable with respect to their effective presentations.

Proof. This is the computability component supplied by the strong universal embedding theorem. ■

Theorem (`jSharp_isComputableMap`). The chosen projection from the universal domain to the sharp universal domain is computable with respect to their effective presentations.

Proof. This is the computability component for the projection supplied by the strong universal embedding theorem. ■

4.9.60 A-sharp (more)

This peer proves that the sharp transform preserves projections, finitarity, and computability, then develops order isomorphisms for function spaces and derives self-similarity equations for domains.

Theorem (`aSharp.le_idMap_of_le`). If a lies below the identity on the universal domain, then its sharp transform also lies below the identity.

Proof. Monotonicity of structural sharp recursion places the inner sharp action below the identity on the sharp domain. Composing with the universal embedding–projection pair preserves the inequality, and that pair's reverse composite lies below the universal identity. ■

Theorem (`aSharp.isFinitary`). If a is a finitary projection, then its sharp transform is finitary.

Proof. The forward and backward sharp combinators exhibit the sharp transform as the projection associated with the sharp fixed neighbourhood system, which has the required finite presentation. ■

Theorem (`aSharp.isComputable`). If a is computable, then its sharp transform is computable.

Proof. The induced inner sharp action is computable because sharp inclusion, sharp pairing, and a are computable. Compose it with the computable universal projection and embedding. ■

Theorem (`toElementMap_aSharp`). On elements, the sharp transform sends x first through the universal projection, then through the inner sharp action, and finally through the universal embedding.

Proof. Element maps carry composition to successive application. ■

Theorem (`isRetraction_aSharp`). If the inner sharp action of a is idempotent, then the sharp transform of a is idempotent.

Proof. In the square of the sharp transform, the middle projection–embedding pair cancels to the identity, and the two remaining inner actions collapse to one by idempotence. ■

Theorem (`isProjection_aSharp`). If a is a projection, then its sharp transform is a projection.

Proof. Idempotence of a gives idempotence of its inner sharp action and hence of its sharp transform; the inequality $a \leq \mathrm{id}$ gives the corresponding inequality for the transform. ■

Theorem (`isFinitaryProjection_aSharp`). The sharp transform of a finitary projection is again a finitary projection.

Proof. The transform is a projection by the preceding result and is finitary by the sharp combinator presentation. ■

Theorem (`ofIso_comp_ofIso_symm`). For an order isomorphism $e : V_0 \cong V_0'$, the approximable maps induced by e^{-1} and then e compose to the identity on V_0'.

Proof. Their element maps apply e^{-1} and then e, which are mutually inverse. ■

Theorem (`funSpaceCongr_hij`). The two function-space maps induced contravariantly by an order isomorphism of source domains and covariantly by an order isomorphism of target domains compose to the identity on the primed function space.

Proof. Composition of exponential maps reduces to composition in the source and target components; both component composites are identities by the inverse laws for the two order isomorphisms. ■

Theorem (`ofIso_symm_comp_ofIso`). For an order isomorphism $e : V_0 \cong V_0'$, the approximable maps induced by e and then e^{-1} compose to the identity on V_0.

Proof. Their element maps apply e and then e^{-1}, which are mutually inverse. ■

Theorem (`funSpaceCongr_hji`). The function-space maps induced in the two opposite directions compose to the identity on the unprimed function space.

Proof. Reduce composition of exponential maps to the source and target component composites, each of which is the identity by the inverse laws. ■

Definition (`orderIsoOfMutualInverse`). Two approximable maps $i : D \to E$ and $j : E \to D$ whose composites are identities determine an order isomorphism between the element posets of D and E.

Proof. Use their element maps as the forward and inverse functions. The composite equations give the inverse laws, and monotonicity in both directions reflects as well as preserves order. ■

Definition (`funSpaceCongrOrderIso`). Order isomorphisms $V_0 \cong V_0'$ and $V_1 \cong V_1'$ induce an order isomorphism $[V_0 \to V_1] \cong [V_0' \to V_1']$.

Proof. Use the exponential maps obtained by transporting arguments contravariantly and values covariantly; the two preceding function-space inverse equations show that these maps are mutual inverses. ■

Theorem (`curry_isomorphic`). The function-space domains $[V_0 \times V_1 \to V_2]$ and $[V_0 \to [V_1 \to V_2]]$ are isomorphic.

Proof. The standard currying order isomorphism supplies the domain isomorphism. ■

Theorem (`funSpace_congr`). Isomorphic source domains and isomorphic target domains have isomorphic function-space domains.

Proof. Choose order isomorphisms witnessing the two domain isomorphisms and apply the induced function-space order isomorphism. ■

Theorem (`funSpace_congr_left`). Replacing the source of a function-space domain by an isomorphic domain preserves its isomorphism type.

Proof. Apply function-space congruence to the given source isomorphism and the identity isomorphism of the target. ■

Theorem (`funSpace_congr_right`). Replacing the target of a function-space domain by an isomorphic domain preserves its isomorphism type.

Proof. Apply function-space congruence to the identity isomorphism of the source and the given target isomorphism. ■

Theorem (`prod_self_isomorphic`). If $D \cong [D \to V]$ and $V \times V \cong V$, then $D \times D \cong D$.

Proof. Replace each copy of D by $[D \to V]$, identify their product with $[D \to V \times V]$, replace $V \times V$ by V, and finally use the inverse of the original isomorphism. ■

Theorem (`funSpace_self_isomorphic`). If $D \cong [D \to V]$ and $V \times V \cong V$, then $D \cong [D \to D]$.

Proof. First obtain $D \times D \cong D$. Replace the codomain D by $[D \to V]$, uncurry to obtain functions on $D \times D$, replace that product by D, and use the original isomorphism; reversing the resulting isomorphism gives the claim. ■

4.9.61 Exercise 8.21 — lists of a projection

NeighbourhoodSystems/RetractsOfTheUniversalDomain/Exercise_8_21.lean

@import "Exercise_8_21.lean"

EXERCISE 8.21. Using the fixed-point construction, show that there is a continuous and computable operator $\lambda a.\, a^{\S}$, such that if a is a finitary projection of U, then

$$D_{a^{\S}} \cong (D_a)^{\S} .$$

The development is with the A-sharp on lists peer.

Theorem (`example_821`). The list-of-projection combinator is finitary when the projection is finitary.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.62 Example C below B

This peer gives an explicit coding that places Scott's domain C inside the binary-sequence domain B, while also recording the evident embedding of B into C.

Theorem (`ExampleCLeB.C_nonempty`). Every neighbourhood of C is nonempty.

Proof. A cone contains its generating string, and a singleton contains its unique string. ■

Definition (`ExampleCLeB.enc`). The encoding of a finite binary string duplicates each bit, sending $b_1 \dots b_n$ to $b_1 b_1 \dots b_n b_n$.

Proof. This recursive prescription uniquely defines the encoding, with the empty string fixed. ■

Definition (`ExampleCLeB.encC`). The terminated encoding of a string is its duplicated-bit encoding followed by the marker 10.

Proof. Appending a marker not produced by a duplicated pair distinguishes terminated codes from ordinary duplicated prefixes. ■

Theorem (`ExampleCLeB.enc_nil`). The encoding of the empty string is empty.

Proof. This is the empty clause of the recursive definition. ■

Theorem (`ExampleCLeB.enc_cons`). Encoding a string beginning with b begins with two copies of b, followed by the encoding of the tail.

Proof. This is the nonempty clause of the recursive definition. ■

Theorem (`ExampleCLeB.encC_cons`). The terminated encoding of $b\sigma$ is bb followed by the terminated encoding of σ.

Proof. Expand the duplicated encoding of a nonempty string and reassociate the terminal marker. ■

Theorem (`ExampleCLeB.encC_nil`). The terminated encoding of the empty string is the marker 10.

Proof. The ordinary encoding is empty, so only the marker remains. ■

Theorem (`ExampleCLeB.enc_append`). Encoding commutes with concatenation.

Proof. Induct on the first string; duplication of its leading bit is compatible with concatenation. ■

Theorem (`ExampleCLeB.enc_length`). The encoded string has twice the length of the original string.

Proof. Induction on the string adds two encoded bits for each original bit. ■

Theorem (`ExampleCLeB.encC_length`). The terminated encoding of σ has length $2|\sigma| + 2$.

Proof. The duplicated encoding contributes $2|\sigma|$ bits and the terminal marker contributes two more. ■

Theorem (`ExampleCLeB.encC_prefix_encC_iff`). One terminated code is a prefix of another exactly when the original strings are equal.

Proof. Compare duplicated bits from the left. A proper extension cannot pass the first terminal marker, whose unequal pair cannot be the beginning of another duplicated block. ■

Theorem (`ExampleCLeB.encC_injective`). Terminated encoding is injective.

Proof. Equality gives a prefix relation between the two terminated codes, and the prefix characterization forces equality of the source strings. ■

Theorem (`ExampleCLeB.enc_prefix_of_prefix`). Prefixes are preserved by duplicated-bit encoding.

Proof. Write the longer string as the shorter string followed by a suffix and use compatibility with concatenation. ■

Theorem (`ExampleCLeB.enc_prefix_encC_iff`). The ordinary encoding of ρ is a prefix of the terminated encoding of σ exactly when ρ is a prefix of σ.

Proof. Successive duplicated pairs recover the corresponding source bits, while the terminal marker prevents any further source bit from being read. ■

Theorem (`ExampleCLeB.enc_prefix_iff`). The ordinary encoding of σ is a prefix of the ordinary encoding of τ exactly when σ is a prefix of τ.

Proof. Preservation is immediate from concatenation; reflection follows by comparing the duplicated leading pairs recursively. ■

Theorem (`ExampleCLeB.enc_injective`). Duplicated-bit encoding is injective.

Proof. Equality of encodings gives prefix relations in both directions, hence prefix relations between the original strings in both directions and therefore equality. ■

Definition (`ExampleCLeB.memD'`). A neighbourhood of the auxiliary system D' is either the cone generated by an ordinary duplicated code or the cone generated by a terminated code.

Proof. These two families encode respectively the cone and singleton neighbourhoods of C. ■

Theorem (`ExampleCLeB.D'_nestedOrDisjoint`). Any two proposed neighbourhoods of D' are nested or disjoint.

Proof. All proposed neighbourhoods are cones, and two cones of finite strings are nested when their generators are prefix-comparable and disjoint otherwise. ■

Definition (`ExampleCLeB.D'`). The auxiliary neighbourhood system D' has all finite binary strings as master neighbourhood and has exactly the ordinary-code and terminated-code cones as neighbourhoods.

Proof. The master cone belongs to the family, every neighbourhood lies in the master set, and the nested-or-disjoint property supplies closure under admissible intersections. ■

Theorem (`ExampleCLeB.D'_mem`). A set is a neighbourhood of D' exactly when it is an ordinary-code cone or a terminated-code cone.

Proof. This is the neighbourhood predicate used in the construction of D'. ■

Theorem (`ExampleCLeB.D'_master`). The master neighbourhood of D' is the set of all finite binary strings.

Proof. This is the chosen master set in the construction of D'. ■

Theorem (`ExampleCLeB.D'_subsystem_B`). The auxiliary system D' is a subsystem of the binary-sequence domain B.

Proof. Its master neighbourhood agrees with that of B, every coded neighbourhood is a cone of B, and an inhabited intersection of two coded cones is the smaller cone by nestedness. ■

Theorem (`ExampleCLeB.cone_encC_subset_cone_enc_iff`). The cone generated by the terminated code of σ is contained in the cone generated by the ordinary code of τ exactly when τ is a prefix of σ.

Proof. Inclusion of cones reverses the prefix order on their generators, and ordinary-code prefixes of a terminated code reflect precisely the original prefix relation. ■

Theorem (`ExampleCLeB.cone_encC_subset_iff`). The terminated-code cone of σ is contained in that of τ exactly when $\sigma = \tau$.

Proof. Cone inclusion reverses prefix, while terminated codes are prefix-comparable only when their source strings are equal. ■

Theorem (`ExampleCLeB.cone_enc_subset_iff`). The ordinary-code cone of σ is contained in that of τ exactly when τ is a prefix of σ.

Proof. Cone inclusion reverses prefix and duplicated-bit encoding both preserves and reflects prefix. ■

Theorem (`ExampleCLeB.cone_ne_singleton`). No cone of finite binary strings is a singleton.

Proof. A cone contains both its generator and the proper extension obtained by appending a bit. ■

Theorem (`ExampleCLeB.not_encC_prefix_enc`). A terminated code is never a prefix of an ordinary duplicated code.

Proof. Comparing duplicated pairs eventually reaches the terminal marker 10, which cannot match a duplicated pair. ■

Theorem (`ExampleCLeB.enc_ne_encC`). No ordinary duplicated code equals a terminated code.

Proof. Equality would make the terminated code a prefix of the ordinary code, contradicting the marker property. ■

Theorem (`ExampleCLeB.not_cone_enc_subset_cone_encC`). An ordinary-code cone is never contained in a terminated-code cone.

Proof. Such cone inclusion would require the terminated generator to prefix the ordinary generator, which is impossible. ■

Definition (`ExampleCLeB.fromD'`). An element of D' determines an element of C: membership of an ordinary-code cone becomes membership of the corresponding cone, and membership of a terminated-code cone becomes membership of the corresponding singleton.

Proof. The cone calculations above show downward closure, master membership, intersection closure, and upward closure for the resulting family of C-neighbourhoods. ■

Definition (`ExampleCLeB.toD'`). An element of C determines an element of D': each cone neighbourhood is sent to its ordinary-code cone, and each singleton neighbourhood to its terminated-code cone.

Proof. The prefix and cone calculations show that the encoded family contains the master neighbourhood and is closed under restriction, inhabited intersections, and enlargement. ■

Theorem (`ExampleCLeB.toD'_mem_enc`). For an element x of C, its image belongs to the ordinary-code cone of κ exactly when x belongs to the cone of κ.

Proof. Ordinary encodings are injective and cannot equal terminated encodings, so only the corresponding cone clause can witness membership. ■

Theorem (`ExampleCLeB.toD'_mem_encC`). For an element x of C, its image belongs to the terminated-code cone of κ exactly when x belongs to the singleton $\{\kappa\}$.

Proof. Terminated encodings are injective and disjoint from ordinary encodings, so only the corresponding singleton clause can witness membership. ■

Theorem (`ExampleCLeB.fromD'_mem_cone`). For an element y of D', its decoded element belongs to the cone of κ exactly when y belongs to the ordinary-code cone of κ.

Proof. Equality of cones identifies their generators, and no cone can equal a singleton. ■

Theorem (`ExampleCLeB.fromD'_mem_singleton`). For an element y of D', its decoded element belongs to the singleton $\{\kappa\}$ exactly when y belongs to the terminated-code cone of κ.

Proof. A cone cannot equal a singleton, while equality of singletons identifies their unique strings. ■

Theorem (`ExampleCLeB.fromD'_toD'`). Decoding after encoding an element of C returns the original element.

Proof. The two elements have identical cone and singleton neighbourhoods by the two encoding membership characterizations, and these exhaust the neighbourhoods of C. ■

Theorem (`ExampleCLeB.toD'_fromD'`). Encoding after decoding an element of D' returns the original element.

Proof. The two elements have identical ordinary-code and terminated-code cone neighbourhoods by the two decoding membership characterizations, and these exhaust the neighbourhoods of D'. ■

Definition (`ExampleCLeB.cdEquiv`). The encoding and decoding maps form an order isomorphism between the elements of C and the elements of D'.

Proof. They are inverse by the preceding two theorems, and inclusion of neighbourhood families is preserved and reflected by the two kinds of coded neighbourhood. ■

Theorem (`ExampleCLeB.B_subsystem_C`). The binary-sequence domain B is a subsystem of C.

Proof. Both have the same master neighbourhood, every cone neighbourhood of B is a neighbourhood of C, and any inhabited intersection of two cones is the smaller cone. ■

Theorem (`ExampleCLeB.B_trianglelefteq_C`). The domain B is isomorphic to a subsystem of C.

Proof. Every subsystem is canonically isomorphic to a subsystem of its ambient domain. ■

Theorem (`ExampleCLeB.C_isomorphic_D'`). The domain C is isomorphic to the auxiliary system D'.

Proof. The order isomorphism between their element domains induces the required domain isomorphism. ■

Theorem (`ExampleCLeB.C_trianglelefteq_B`). The domain C is isomorphic to a subsystem of B.

Proof. Use D' as the subsystem of B and the preceding isomorphism between C and D'. ■

4.9.63 Exercise 8.22 — comparing B and C

Which of the two relations hold:

$$B \trianglelefteq C \quad \text{or} \quad C \trianglelefteq B\,?$$

Or do they both hold? In general if we use domain equations

$$D = T(D) + S(D)\,, \quad \text{and}$$

$$E = T(E)\,,$$

will $E \trianglelefteq D$ hold? What projections do you see in the examples in 6.2?

The development is with the Example C below B peer.

Theorem (`example_822`). Scott's sequence domain C is a subdomain of the bit domain B.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.64 Fix operator

This peer constructs the least fixed-point operation on endomaps, proves that it preserves finitary projections under a natural closure hypothesis, and identifies the resulting fixed domains.

Theorem (`FixOp.eq_bot_of_fixed_constMap_bot`). The only element fixed by the constant map with value bottom is bottom itself.

Proof. The image of every element under the constant map is bottom, so the fixed-point equation immediately identifies the element with bottom. ■

Theorem (`FixOp.uniqueFixedConstMapBot`). The fixed-point type of the constant-bottom map has exactly one element.

Proof. Bottom is fixed, and every fixed element is bottom by the preceding fact. ■

Definition (`FixOp.finitaryWitnessEquivBot`). The fixed-point poset of the constant-bottom map is order-isomorphic to the one-element neighbourhood system.

Proof. Both posets have a unique element, so the unique maps in both directions are mutually inverse and preserve the order. ■

Definition (`FixOp.fixOp`). For an endomap t of the function-space domain $[E \to E]$, its fixed-point operator is the approximable endomap of E represented by the least fixed element of t.

Proof. Convert the least fixed element of t from a function-space element to its corresponding approximable map. ■

Definition (`FixOp.tOp`). An operator t on endomaps acts on an endomap a by applying t to the function-space element represented by a, then converting the result back to an approximable map.

Proof. This is the transport of the element action of t across the correspondence between function-space elements and approximable maps. ■

Definition (`FixOp.Fix`). For an endomap $a : E \to E$, $\mathrm{Fix}(a)$ is the ordered type of elements y satisfying $a(y) = y$.

Proof. Take the subtype of the element poset cut out by the fixed-point equation, with its inherited order. ■

Theorem (`FixOp.constMap_bot_le_idMap`). The constant-bottom endomap lies below the identity endomap.

Proof. Every value of the constant map is bottom, and bottom lies below every element. ■

Theorem (`FixOp.isRetraction_constMap_bot`). The constant-bottom endomap is idempotent.

Proof. Applying the map once or twice always returns bottom. ■

Theorem (`FixOp.isProjection_constMap_bot`). The constant-bottom endomap is a projection.

Proof. It is idempotent and lies below the identity. ■

Theorem (`FixOp.isFinitaryProjection_constMap_bot`). The constant-bottom endomap is a finitary projection.

Proof. Its fixed-point poset is order-isomorphic to the one-element neighbourhood system, which supplies a finite witness for the projection. ■

Theorem (`FixOp.iterElem_succ'`). The $(n+1)$-st approximation in the iteration of t is obtained by applying t to the n-th approximation.

Proof. Successor iteration is composition with t, and element maps carry composition to successive application. ■

Theorem (`FixOp.iterElem_zero'`). The zeroth approximation in the iteration of t is the bottom element of the function-space domain.

Proof. Zeroth iteration is the identity, evaluated at bottom. ■

Theorem (`FixOp.rel_master_of_mem`). If X is a neighbourhood of E, then every approximable endomap relates X to the master neighbourhood.

Proof. Start with the map's master relation and use monotonicity, since X is contained in the master neighbourhood. ■

Theorem (`FixOp.tOp_fixOp`). The endomap obtained as the least fixed point of t is fixed by the induced action of t.

Proof. The least fixed element of t is fixed by t, and the element–map correspondence preserves this equation. ■

Theorem (`FixOp.tOp_toApproxMap`). Acting on the approximable map represented by a function-space element φ yields the approximable map represented by $t(\varphi)$.

Proof. The two conversions between function-space elements and approximable maps are inverse. ■

Theorem (`FixOp.toApproxMap_bot_eq_constMap`). The approximable map represented by the bottom function-space element is the constant-bottom map.

Proof. A relation belongs to the bottom function exactly when its input is a neighbourhood and its output is bottom; this is precisely the relation of the constant-bottom map. ■

Theorem (`FixOp.isFinitaryProjection_fixOp`). Suppose the action induced by t sends every finitary projection to a finitary projection. Then the least fixed-point endomap of t is itself a finitary projection.

Proof. Beginning with the constant-bottom finitary projection, induction shows that every finite iterate is finitary. The least fixed element is the directed supremum of these iterates, and the finitary core operation fixes each iterate and commutes with this directed supremum; hence it fixes the limit, which characterizes a finitary projection. ■

Theorem (`FixOp.fixedDomain_fixOp_iso_T`). Suppose the induced action of t preserves finitary projections, and the fixed domain of its value at each finitary projection a is order-isomorphic to a specified domain $T(a)$. Then the fixed domain of the least fixed-point endomap is order-isomorphic to T evaluated at that endomap.

Proof. The least fixed-point endomap is finitary and is fixed by the induced action, so specialize the assumed family of order isomorphisms to it. ■

Theorem (`FixOp.fixedNbhd_fixOp_subsystem`). Under the same preservation hypothesis, if a is a finitary projection and the induced action sends a below itself, then the fixed neighbourhood system of the least fixed-point endomap is a subsystem of the fixed neighbourhood system of a.

Proof. The pre-fixed-point inequality implies, by leastness, that the least fixed element of t lies below the element represented by a. Transporting this inequality to approximable maps and using the order characterization of fixed neighbourhood subsystems for finitary projections gives the result. ■

4.9.65 Exercise 8.23 — initial algebra inside U

NeighbourhoodSystems/RetractsOfTheUniversalDomain/Exercise_8_23.lean

@import "Exercise_8_23.lean"

EXERCISE 8.23. Suppose a construct T on domains can be made into a computable operator $t : (U \to U) \to (U \to U)$ so that whenever $a : U \to U$ is a finitary projection, then so is $t(a)$ and

$$D_{t(a)} \cong T(D_a) \,.$$

Does it follow that $\|t\| = \mathrm{fix}(t)$ is such that

$$D_{\|t\|} \cong T(D_{\|t\|})$$

really is the initial solution of the domain equation with respect to projections? Since t is computable, will this solution be effectively given?

The development is with the Fix operator peer.

Theorem (`example_823`). Inside U, the initial algebra for the given operator exists as a retract.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.66 Coupled fixed points

This peer extends least-fixed-point recursion to two mutually dependent endomaps, proves finitarity and leastness of the coupled solution, and records two countable domains that therefore embed in the universal domain.

Definition (`CoupledFixedPoints.PairSpace`). The parameter space for coupled recursion is the product of two copies of the endomap function space $[E \to E]$.

Proof. Form the product neighbourhood system of the two function spaces. ■

Definition (`CoupledFixedPoints.aOp`). Given two operators s and t on pairs of endomaps, a_n is the first component of the n-th approximation to the least fixed point of their paired operator.

Proof. Iterate the paired operator from bottom, take the first coordinate, and read it as an approximable endomap of E. ■

Definition (`CoupledFixedPoints.aStar`). The first coupled fixed-point endomap a^* is the first component of the least fixed element of the paired operator determined by s and t.

Proof. Take the first coordinate of the paired least fixed element and convert it to an endomap of E. ■

Definition (`CoupledFixedPoints.bOp`). Given s and t, b_n is the second component of the n-th approximation to the least fixed point of their paired operator.

Proof. Iterate the paired operator from bottom, take the second coordinate, and read it as an approximable endomap of E. ■

Definition (`CoupledFixedPoints.bStar`). The second coupled fixed-point endomap b^* is the second component of the least fixed element of the paired operator determined by s and t.

Proof. Take the second coordinate of the paired least fixed element and convert it to an endomap of E. ■

Definition (`CoupledFixedPoints.binOp`). An operator f on pairs of endomaps acts on a, b by applying f to the function-space pair represented by a, b, then reading the result as an endomap of E.

Proof. Pair the function-space elements corresponding to a and b, apply f, and use the element–map correspondence. ■

Theorem (`CoupledFixedPoints.fst_mono`). First-coordinate projection on the pair space is monotone.

Proof. Inclusion of pair elements preserves every neighbourhood witnessed in the first coordinate. ■

Theorem (`CoupledFixedPoints.iterElem_pair_eq_pair`). Every iterate of the paired operator is the pair of the function-space elements represented by a_n and b_n.

Proof. An element of a product is recovered from its first and second coordinates, and the conversions between function-space elements and approximable maps are inverse. ■

Theorem (`CoupledFixedPoints.iterElem_succ_pair`). The successor iterate of the paired operator is its value at the preceding iterate.

Proof. Successor iteration is composition with the operator, and the element action of a composite is successive application. ■

Theorem (`CoupledFixedPoints.aOp_succ`). The first approximation satisfies $a_{n+1} = s(a_n, b_n)$.

Proof. Express the successor iterate as one application of the paired operator, identify its first coordinate, and use the decomposition of the preceding iterate into a_n, b_n. ■

Theorem (`CoupledFixedPoints.bOp_succ`). The second approximation satisfies $b_{n+1} = t(a_n, b_n)$.

Proof. Express the successor iterate as one application of the paired operator, identify its second coordinate, and use the decomposition of the preceding iterate into a_n, b_n. ■

Theorem (`CoupledFixedPoints.iterElem_zero_pair`). The zeroth iterate of the paired operator is the bottom element of the pair space.

Proof. Zeroth iteration is the identity map evaluated at bottom. ■

Theorem (`CoupledFixedPoints.pair_bot_bot`). Pairing the two bottom function-space elements gives the bottom element of the pair space.

Proof. A product neighbourhood belongs to this pair exactly when both coordinates are bottom, which is precisely the defining condition for the product bottom. ■

Theorem (`CoupledFixedPoints.pairSpace_bot_fst`). The first coordinate of the bottom pair is the bottom function-space element.

Proof. Write the bottom pair as the pair of two bottoms and take its first coordinate. ■

Theorem (`CoupledFixedPoints.aOp_zero`). The initial first approximation a_0 is the constant-bottom endomap.

Proof. The zeroth paired iterate is bottom, its first coordinate is bottom, and the bottom function-space element represents the constant-bottom map. ■

Theorem (`CoupledFixedPoints.pairSpace_bot_snd`). The second coordinate of the bottom pair is the bottom function-space element.

Proof. Write the bottom pair as the pair of two bottoms and take its second coordinate. ■

Theorem (`CoupledFixedPoints.bOp_zero`). The initial second approximation b_0 is the constant-bottom endomap.

Proof. The zeroth paired iterate is bottom, its second coordinate is bottom, and the bottom function-space element represents the constant-bottom map. ■

Theorem (`CoupledFixedPoints.isFinitaryProjection_chain`). If $s(a, b)$ and $t(a, b)$ are finitary projections whenever a and b are, then every pair a_n, b_n in the approximation chain consists of finitary projections.

Proof. Induct on n. At zero both maps are constant bottom; at a successor use the two recursion equations and the assumed closure property. ■

Theorem (`CoupledFixedPoints.snd_mono`). Second-coordinate projection on the pair space is monotone.

Proof. Inclusion of pair elements preserves every neighbourhood witnessed in the second coordinate. ■

Theorem (`CoupledFixedPoints.isFinitaryProjection_aStar_bStar`). Under the same closure hypothesis, both coupled least fixed-point maps a^* and b^* are finitary projections.

Proof. Each coordinate chain is directed and consists of finitary projections. The finitary core fixes every stage and commutes with the directed supremum; since each coordinate of the paired least fixed point is that supremum, both limit maps satisfy the characterization of finitary projections. ■

Theorem (`CoupledFixedPoints.fixedNbhd_aStar_bStar_subsystem`). Suppose the coupled operator preserves pairs of finitary projections. If finitary projections a, b satisfy $s(a, b) \leq a$ and $t(a, b) \leq b$, then the fixed neighbourhood systems of a^*, b^* are respectively subsystems of those of a, b.

Proof. The pair represented by a, b is a pre-fixed point of the paired operator, so leastness places the paired least fixed point below it coordinatewise. Convert these inequalities to the endomaps a^*, b^*, then use the order characterization of fixed-neighbourhood subsystems for finitary projections. ■

Theorem (`CoupledFixedPoints.toElementMap_fixElement_fst`). Applying s to the paired least fixed element yields its first coordinate.

Proof. The paired least fixed element is fixed by the paired operator, whose first coordinate is the value of s. ■

Theorem (`CoupledFixedPoints.binOp_aStar_bStar_left`). The coupled solution satisfies $s(a^*, b^*) = a^*$.

Proof. The pair represented by a^*, b^* is the paired least fixed element, and the preceding coordinate equation identifies the value of s. ■

Theorem (`CoupledFixedPoints.toElementMap_fixElement_snd`). Applying t to the paired least fixed element yields its second coordinate.

Proof. The paired least fixed element is fixed by the paired operator, whose second coordinate is the value of t. ■

Theorem (`CoupledFixedPoints.binOp_aStar_bStar_right`). The coupled solution satisfies $t(a^*, b^*) = b^*$.

Proof. The pair represented by a^*, b^* is the paired least fixed element, and the preceding coordinate equation identifies the value of t. ■

Theorem (`CoupledFixedPoints.fixedDomain_aStar_bStar_iso`). Assume the coupled operator preserves finitary projections. If the fixed domain of $s(a, b)$ is always order-isomorphic to $S(a, b)$, and that of $t(a, b)$ to $T(a, b)$, for finitary a, b, then the fixed domains of a^*, b^* are respectively order-isomorphic to $S(a^*, b^*)$ and $T(a^*, b^*)$.

Proof. The coupled solution consists of finitary projections and satisfies both fixed-point equations. Specialize the two assumed families of order isomorphisms and replace their source endomaps using those equations. ■

Theorem (`RegularLanguage.Ssys_countable`). The type of regular-language systems is countable.

Proof. Every such system is denoted by a finite symbolic expression. Choose a denoting expression for each system; expressions form a countable type, so their surjective denotation makes the systems countable. The equivalent presentation by the stated membership predicate has the same cardinality. ■

Theorem (`P4.P4_embeds`). The neighbourhood system P_4 is a retract of the universal domain.

Proof. Apply the universal embedding theorem to this countable neighbourhood system. ■

Theorem (`RegularLanguage.Ssys_embeds`). The neighbourhood system of regular-language systems is a retract of the universal domain.

Proof. Its underlying type is countable, so the universal embedding theorem applies. ■

4.9.67 Exercise 8.24 — coupled domain equations

NeighbourhoodSystems/RetractsOfTheUniversalDomain/Exercise_8_24.lean

@import “Exercise_8_24.lean”

EXERCISE 8.24. Suppose S and T are two (binary-argument) constructs on domains that can be made into computable operators on projections of the universal domain. Show that we can therefore find a pair of effectively presented domains such that

$$D \cong S(D,E) \quad \text{and} \quad E \cong T(D,E).$$

The development is with the Coupled fixed points peer.

Theorem (`example_824`). The coupled fixed-point domain is effectively given.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.68 Reflexive domain

This peer carries out the reflexive-domain construction of Exercise 8.25. It builds a finitary projection whose fixed-point domain is universal and isomorphic to its own function space.

Theorem (`trianglelefteq_iterSys`). Every neighbourhood system V is a retract-subdomain of its countable power $V^{\mathbb{N}}$.

Proof. Embed an element as the constant sequence and project a sequence to its first coordinate. Projection after embedding is the identity, while embedding after projection lies below the identity. ■

Theorem (`example_825_embed`). For every V, one has $V \trianglelefteq V^{\mathbb{N}}$.

Proof. This is the preceding constant-sequence projection pair, uniformly quantified over V. ■

Definition (`arrowReindexOrderIso`). A bijection between index types induces an order isomorphism between the corresponding spaces of indexed families by reindexing.

Definition (`sumArrowOrderIso`). A family indexed by a disjoint sum is order-isomorphic to a pair of families indexed by the two summands.

Definition (`interleaveOrderIso`). A pair of countable families is order-isomorphic to one countable family by interleaving their coordinates.

Definition (`powProdOrderIso`). The product $V^{\mathbb{N}} \times V^{\mathbb{N}}$ is order-isomorphic to $V^{\mathbb{N}}$, by viewing both powers as sequences and interleaving them.

Theorem (`pow_prod_isomorphic`). The product of two copies of the countable power of V is isomorphic, as a domain, to that countable power.

Proof. The interleaving order isomorphism between their element orders induces the required domain isomorphism. ■

Theorem (`example_825_pow`). For every V, $V^{\mathbb{N}} \times V^{\mathbb{N}} \cong V^{\mathbb{N}}$.

Proof. Apply the preceding product-of-powers isomorphism. ■

Definition (`isoOfUnique`). Any two ordered types having exactly one element are order-isomorphic by the unique maps between them.

Theorem (`uniqueApproximableMapUnitSys`). There is exactly one approximable endomap of the one-point neighbourhood system.

Proof. Every such map has the same action on the sole element, hence equals the identity map. ■

Theorem (`uniqueFunSpaceUnitSys`). The function-space domain from the one-point system to itself has exactly one element.

Proof. Its elements correspond to approximable maps of the one-point system, of which there is exactly one. ■

Theorem (`isomorphic_of_unique`). Neighbourhood systems whose element domains each have exactly one element are isomorphic.

Proof. Their element orders are related by the unique order isomorphism between singleton ordered types. ■

Theorem (`funSpace_unitSys_isomorphic`). The function space from the one-point system to itself is isomorphic to the one-point system.

Proof. Both element domains have exactly one element. ■

Theorem (`example_825_unit`). The one-point domain satisfies $1^1 \cong 1$.

Proof. This is the preceding singleton function-space isomorphism. ■

Definition (`RDom`). Let R be the product $[U \to U] \times ([U \to U] \times U)$, the domain of triples consisting of two universal endomaps and one universal element.

Definition (`RMap`). For $c : U \to U$, define a map $R \to U$ sending (ψ, φ, x) to $c(\varphi(\psi(x)))$.

Definition (`curryOnceC`). Currying the preceding map once produces a map from the first function argument to a function of the remaining function argument and universal element.

Definition (`fixedNbhd_elementIso_fix`). For a finitary projection a, the element domain of its fixed-neighbourhood system is order-isomorphic to the subtype of elements fixed by a.

Definition (`lamOp`). For $c : U \to U$, twice currying the map $(\psi, \varphi, x) \mapsto c(\varphi(\psi(x)))$ gives an operator sending a to the curried action of composition around a and c.

Definition (`presentationIterU`). Choose a computable presentation of the countable power $U^{\mathbb{N}}$, which is effectively given because U is effectively given.

Definition (`cInj`). Choose the embedding of $U^{\mathbb{N}}$ into U supplied by universality of U.

Definition (`cProj`). Choose the corresponding projection from U onto $U^{\mathbb{N}}$.

Definition (`cCombinator`). The combinator projection on U is embedding after projection for the chosen projection pair between $U^{\mathbb{N}}$ and U.

Definition (`TArrow`). For an endomap a of U, associate the function space from the fixed-neighbourhood domain of a to the fixed-neighbourhood domain of the combinator projection.

Theorem (`cProj_comp_cInj`). Projecting after embedding $U^{\mathbb{N}}$ is the identity.

Proof. This is the retraction equation of the chosen universal projection pair. ■

Definition (`cElementIso`). The elements of $U^{\mathbb{N}}$ are order-isomorphic to the elements of U fixed by the combinator projection.

Definition (`tOpMap`). For $c : U \to U$, compose the curried composition operator with the map induced contravariantly and covariantly by the universal decoding and encoding maps, obtaining an endomap of the function-space domain.

Theorem (`cInj_comp_cProj_le`). Embedding after projecting U lies below the identity on U.

Proof. This is the order inequality of the chosen universal projection pair. ■

Theorem (`isFinitary_cCombinator`). The combinator projection is finitary.

Proof. It arises from a projection pair whose retract is the effectively given domain $U^{\mathbb{N}}$. ■

Theorem (`isRetraction_cCombinator`). The combinator projection is idempotent.

Proof. In its square, the middle projection-after-embedding composite is the identity. ■

Theorem (`isProjection_cCombinator`). The combinator endomap is a projection.

Proof. It is idempotent and lies below the identity. ■

Theorem (`isFinitaryProjection_cCombinator`). The combinator endomap is a finitary projection.

Proof. Combine its projection property with its finitarity. ■

Theorem (`fixedNbhd_cCombinator_isomorphic`). The fixed-neighbourhood domain of the combinator projection is isomorphic to $U^{\mathbb{N}}$.

Proof. Both domains are order-isomorphic to the fixed-point subtype of the same projection. ■

Theorem (`hVV_cCombinator`). The product of two copies of the combinator fixed-neighbourhood domain is isomorphic to that domain.

Proof. Transport both factors to $U^{\mathbb{N}}$, interleave the two countable powers, and transport back. ■

Theorem (`toElementMap_RMap`). The triple map determined by c sends (ψ, φ, x) to $c(\varphi(\psi(x)))$.

Proof. Evaluate the projections, pairings, and two function applications in its defining composite. ■

Theorem (`toApproxMap_lamOp`). Applying the curried composition operator determined by c to the function represented by a, then decoding the result, yields the exponential action induced by a and c.

Proof. Successive applications of currying reduce the statement to the explicit triple-value formula, which is exactly composition first by a and finally by c. ■

Theorem (`tOp_tOpMap`). The fixed-point transformer associated with the operator determined by c, evaluated at a, is the arrow combinator formed from a and c.

Proof. Decode the transformed function-space element and use the preceding identification of the curried operator with the exponential action. ■

Theorem (`hT_TArrow`). For every finitary projection a, the fixed points of its transformed arrow combinator are order-isomorphic to the elements of the function space from the fixed domain of a to the fixed domain of the combinator projection.

Proof. The transformer is the arrow combinator, whose fixed-point theorem identifies its fixed points with the indicated function-space domain. ■

Theorem (`ht_tOpMap`). If c is a finitary projection, then the transformer determined by c sends every finitary projection to a finitary projection.

Proof. The transformer is the arrow combinator, and arrow combinators preserve finitary projections in both arguments. ■

Theorem (`Dsol_isomorphic_funSpace_cCombinator`). Let D be the fixed-neighbourhood domain of the least fixed projection generated by the transformer for the combinator projection. Then $D \cong [D \to C]$, where C is the combinator fixed-neighbourhood domain.

Proof. The transformer preserves finitary projections, so its fixed projection is finitary. Identify the fixed-neighbourhood elements with its fixed points, then apply the fixed-domain theorem and the preceding arrow-family isomorphism. ■

Theorem (`U_trianglelefteq_Dsol`). The universal domain U is a retract-subdomain of the solution domain D.

Proof. Pass successively from U into $U^{\mathbb{N}}$, then into C, then into the constant-function subdomain of $[D \to C]$, and finally transport along $[D \to C] \cong D$. ■

Theorem (`exercise_8_25_main`). The solution domain D is isomorphic to its own function space $[D \to D]$.

Proof. The isomorphism $D \cong [D \to C]$, together with $C \times C \cong C$, yields the standard reflexive-domain self-function-space isomorphism. ■

Theorem (`exercise_8_25_universal`). The solution domain D is universal: $U \trianglelefteq D$.

Proof. This is the retract chain from the universal domain into the constructed solution domain. ■

4.9.69 Exercise 8.25 — reflexive function space

The problem is to find non-trivial solutions to the domain equation

$$(\spadesuit) \qquad D \cong D \to D.$$

Show that the "obvious" solution by retracts is of no use because

$$1 \to 1 = 1$$

for projections. Change the method as follows. Show first

$$U^\infty \times U^\infty \cong U^\infty.$$

Next solve

$$D \cong D \to U^\infty$$

and remark that $U \lhd D$; so D is universal and non-trivial. Finally prove $(\spadesuit)$ for this D. (Hint: First show

$$D \times D \cong D,$$

and then show D satisfies $(\spadesuit)$.) Is this D effectively given?

The development is with the Reflexive domain peer.

Theorem (`example_825`). A non-trivial reflexive function space exists and contains U as a retract.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.70 U apply and U lam

This peer gives application and abstraction directly in the universal domain and formalizes the sandwich calculation underlying the interpretation of typed abstraction and application.

Definition (`Uapply`). Universal application decodes its first argument as a continuous self-map of U and evaluates that map at its second argument.

Definition (`Ulam`). Universal abstraction encodes a continuous self-map of U, regarded as an element of the function-space domain, back into U.

Definition (`translateAbs`). Given endomaps a and b, the translation of a body f is the composite $b \circ f \circ a$.

Theorem (`Uapply_Ulam`). Applying the universal abstraction of a map f to x gives $f(x)$.

Proof. Decoding immediately after encoding is the identity on the function-space domain, so function-space evaluation reduces to evaluation of f at x. ■

Theorem (`translateAbs_idMap`). Translating the identity body between a and b gives the composite $b \circ a$.

Proof. Composition with the identity does not change the intervening map. ■

Theorem (`example_826`). For every neighbourhood system and endomaps a, b, translating the identity body yields $b \circ a$.

Proof. This is the preceding identity-body calculation, uniformly quantified over the neighbourhood system and the two maps. ■

Theorem (`translateAbs_sandwich`). If a and b are retractions, then every translated body $f' = b \circ f \circ a$ satisfies the sandwich equation $b \circ f' \circ a = f'$.

Proof. Associativity gathers the two copies of a and the two copies of b; idempotence of the retractions removes the repetitions. ■

Theorem (`translateApp_hasType`). Suppose f satisfies $b \circ f \circ a = f$. If x is fixed by a, then $f(x)$ is fixed by b.

Proof. Evaluate the sandwich equation at x and use the assumption $a(x) = x$. ■

4.9.71 Exercise 8.26 — untyped calculus in U

Discuss in more detail the "pay-off" for U, namely the translation of "untyped" λ-calculus into U as shown by the equations at the end of the lecture after the proof of 8.9. In particular show how the whole of the **typed** λ-calculus can be retranslated back into U with the aid of projections. (Hint: Whenever you want to write

$$f : D_a \to D_b,$$

write instead

$$f = b \circ f \circ a,$$

where a, b are finitary projections. Whenever you want to form a λ-abstraction

$$\lambda x^{D_a}.\, \sigma,$$

where σ is of type D_b, instead form

$$\lambda x.\, b(\sigma'[a(x)/x]),$$

where σ' is the further translation of σ into untyped λ-calculus. Be sure to show that this result "has the right type" in the sense defined above.)

The development is with the U apply and U lam peer.

Theorem (`example_826`). Untyped application and lambda combinators behave as in the exercise.

Proof. By assembling the peer lemmas named in the packaging module. ■

4.9.72 Polymorphic type

This peer develops Scott's dependent-product construction for polymorphic types. Its central result is that the function-space operator obtained by decoding fibre codes is a finitary projection.

Definition (`PolymorphicType`). A code assignment $d : U \to U$ is polymorphic when it is unchanged by projecting both its argument and its value to the universal subdomain of type codes: $\mathrm{sub} \circ d \circ \mathrm{sub} = d$.

Definition (`scFamily`). For $t \in U$, the Scott family consists of valid neighbourhoods T which contain t and are self-related by the universal subprojection.

Theorem (`instNonemptyScFamily`). The Scott family of every element is nonempty.

Proof. The master neighbourhood contains every element and is related to itself by every approximable map. ■

Definition (`scPrincipal`). Each member T of the Scott family determines the principal element generated by the evidence that t belongs to T.

Theorem (`toElementMap_mem_fix_of_isRetraction_sandwich`). If a is a retraction, every value of the sandwich $a \circ g \circ a$ is fixed by a.

Proof. Applying a once more introduces $a \circ a$, which contracts to a by idempotence. ■

Theorem (`polymorphicType_apply_mem_fix`). Every value of a polymorphic code assignment is fixed by the universal subprojection.

Proof. The polymorphic sandwich equation identifies the assignment with a sandwich by the subprojection; the preceding retraction argument then applies. ■

Theorem (`isFinitaryProjection_toApproxMap_jArrow_of_fix`). If w is fixed by the universal subprojection, then the self-map decoded from w is a finitary projection.

Proof. The fixed-point equation transfers through decoding to the function-space subprojection, whose fixed points are exactly the finitary projections. ■

Theorem (`isFinitaryProjection_decode_subU`). Decoding the subprojection of any universal element yields a finitary projection.

Proof. The image of a retraction is fixed by that retraction, so the preceding fixed-point criterion applies. ■

Theorem (`toElementMap_piDUncurried`). At a pair (φ, t), the uncurried dependent-product operator decodes the projected code $d(\mathrm{sub}(t))$ and applies that fibre projection to the value $\varphi(\mathrm{sub}(t))$.

Proof. Evaluate the pairing, projections, and function-space evaluation in the defining composite. ■

Theorem (`toElementMap_piDApply`). For maps $d, f : U \to U$, dependent-product application at t is the fibre projection decoded from $d(\mathrm{sub}(t))$, applied to $f(\mathrm{sub}(t))$.

Proof. This is the elementwise evaluation of the paired composite defining dependent-product application. ■

Theorem (`toApproxMap_toElementMap_piD`). Decoding the image of a function-space element φ under the dependent-product operator gives dependent-product application to the map represented by φ.

Proof. Currying identifies evaluation of the dependent-product operator at φ with the corresponding section of its uncurried form. ■

Theorem (`piD_rel_iff`). A function-space neighbourhood X is related to W by the dependent-product operator exactly when both are valid and the section determined by the principal element of X belongs to W.

Proof. This is the neighbourhood relation for a curried approximable map. ■

Theorem (`gSection_piDUncurried_rel_iff`). The section determined by a valid function neighbourhood X relates a valid argument neighbourhood Y to Z exactly when applying the corresponding dependent-product map to the principal element of Y belongs to Z.

Proof. The section relation is evaluation of the uncurried map at the two principal elements, and the explicit value formula identifies this with dependent-product application. ■

Theorem (`piD_toElementMap_mem_iff`). A neighbourhood Y belongs to the image of x under the dependent-product operator exactly when Y is valid and the dependent-product application represented by x belongs to Y.

Proof. Decode the image as an approximable map and use the membership characterization of its representing filter. ■

Theorem (`hii_easy_direction`). If $x \in X$, $X \subseteq Y$, and X is self-related by the dependent-product operator, then the image of x belongs to every valid Y.

Proof. The self-related neighbourhood X supplies the finite witness required for image membership, and upward closure carries it to Y. ■

Theorem (`subU_principal_eq_of_rel_self`). If a valid neighbourhood T is self-related by the universal subprojection, then its principal element is fixed by that projection.

Proof. The projection lies below the identity for one inequality; self-relatedness places the principal element below its projected image for the reverse inequality. ■

Theorem (`exists_rel_self_subset_of_mem`). If t is fixed by the universal subprojection and $t \in T_0$, then there is a self-related neighbourhood T containing t with $T \subseteq T_0$.

Proof. Apply the finite-neighbourhood formula for the finitary universal subprojection to the membership of its fixed value in T_0. ■

Theorem (`scFamily_directed`). The principal elements indexed by the Scott family of a fixed point t form a directed family.

Proof. Intersect the two given neighbourhoods, refine that intersection to a self-related neighbourhood containing t, and use inclusion reversal for principal elements. ■

Theorem (`eq_iSupDirected_scPrincipal`). A fixed point t of the universal subprojection is the directed supremum of the principal elements indexed by its Scott family.

Proof. Every neighbourhood of t has a self-related refinement and therefore occurs above one indexed principal; conversely, every neighbourhood of an indexed principal contains t by upward closure. ■

Theorem (`isFinitaryProjection_piD_of_formula`). If image membership for the dependent-product operator is characterized by valid neighbourhoods containing a self-related finite witness, then that operator is a finitary projection.

Proof. The assumed equivalence is precisely the finite-neighbourhood criterion for a finitary projection. ■

Theorem (`le_idMap_piD`). The dependent-product operator lies below the identity on the function-space domain.

Proof. Pointwise, each decoded fibre map is a projection and hence decreases its argument; projecting the input type code also decreases it, and monotonicity of the represented function completes the comparison. ■

Theorem (`piDApply_toElementMap_eq`). Evaluating dependent-product application at the projection of t uses the same decoded fibre projection and the same projected argument as evaluating its explicit formula at t.

Proof. Idempotence removes the repeated universal subprojection. ■

Theorem (`isRetraction_piD`). The dependent-product operator is a retraction.

Proof. After decoding function-space elements, applying the operator twice repeats at each argument the same decoded finitary projection; its idempotence collapses the second application. ■

Theorem (`isProjection_piD`). The dependent-product operator is a projection.

Proof. It is a retraction and lies below the identity by the preceding two results. ■

Theorem (`piDType_monotone`). If $s \leq s'$, then the fibre projection at s lies below the fibre projection at s'.

Proof. The fibre-code map is monotone, and decoding function-space elements preserves order. ■

Theorem (`piD_rel_self_iff`). A function neighbourhood X is self-related by the dependent-product operator exactly when X is valid and its associated section belongs to X.

Proof. Specialize the general relation characterization to equal source and target neighbourhoods. ■

Theorem (`toElementMap_piDTypeMap`). The fibre-code map sends s to the decoded function-space element represented by the projected code $d(s)$.

Proof. Evaluate the composite defining the fibre-code map. ■

Theorem (`isFinitaryProjection_piDType`). Every fibre map selected by a code assignment is a finitary projection.

Proof. Its code is first passed through the universal subprojection, and decoding any such projected code yields a finitary projection. ■

Theorem (`toElementMap_piDApply'`). Dependent-product application at t is the fibre projection indexed by $\mathrm{sub}(t)$, applied to $f(\mathrm{sub}(t))$.

Proof. Substitute the elementwise formula for the fibre-code map into the explicit formula for dependent-product application. ■

Theorem (`exists_X_of_mem_step`). If dependent-product application at x belongs to a one-step function neighbourhood from Y_0 to Z_0, then there is a function neighbourhood X containing x, contained in that step neighbourhood, and self-related by the dependent-product operator.

Proof. Approximate the projected argument by the directed Scott family, use finitarity of the selected fibre projection to obtain a self-related output neighbourhood, choose a common upper approximation, and form the resulting step neighbourhood. Its defining relation gives self-relatedness. ■

Theorem (`exists_X_of_mem_stepFun`). The same finite self-related witness exists when the target is a function neighbourhood formed from a finite list of step conditions.

Proof. Induct over the list. The empty list uses the master neighbourhood; for a new condition, intersect its witness with the inductive witness and use closure of the relation under intersection on the right. ■

Theorem (`hii_hard_direction`). If dependent-product application at x belongs to a valid function neighbourhood Y, then Y contains a self-related function neighbourhood X containing x.

Proof. Every valid function neighbourhood is presented by a finite list of step conditions, to which the preceding finite-list construction applies. ■

Theorem (`hii_piD`). The image of x under the dependent-product operator belongs to Y exactly when Y is valid and contains a self-related function neighbourhood X containing x.

Proof. The forward implication combines the image-membership formula with the hard direction; the reverse implication is the easy finite-witness direction. ■

Theorem (`isFinitaryProjection_piD`). For every code assignment d, the dependent-product operator determined by d is a finitary projection.

Proof. Its image-membership equivalence is the finite-neighbourhood formula required by the general criterion for finitary projections. ■

4.9.73 Infinite product on D

This peer constructs, on the function-space domain, the projection that interprets a dependent product whose fibres are coded by elements of the universal domain.

Definition (`piDApply`). Given a code assignment d and a map $f : U \to U$, define a new map by first projecting the argument to the subdomain of type codes, applying d, decoding the resulting code as a finitary projection, and applying that projection to f at the projected argument.

Definition (`piDUncurried`). The uncurried dependent-product operator sends a pair (f, t) to the value obtained by decoding the projected code $d(\mathrm{sub}(t))$ and applying its projection to $f(\mathrm{sub}(t))$.

Definition (`piD`). The dependent-product projection on the function-space domain is the currying of the uncurried dependent-product operator.

Definition (`piDTypeMap`). For a code assignment d, the associated fibre map sends a universal-domain element through d, projects the result to a valid code, and decodes that code as an element of the function-space domain.

Definition (`piDType`). The fibre projection at s is the approximable map represented by the decoded fibre code at s.

4.9.74 Sub on U

This peer transports the projection onto finitary projections from the function-space domain to the universal domain, and identifies its fixed points with the continuous self-maps lying below the identity.

Theorem (`jArrow_comp_iArrow_apply`). Decoding an encoded function-space element returns that element.

Proof. The decoding map is a left inverse of the encoding map, so their composite acts as the identity. ■

Definition (`subU`). The universal subprojection is obtained by decoding a universal element as a function, projecting that function to the finitary projections, and encoding the result back into U.

Theorem (`subU.toElementMap_eq`). On an element w, the universal subprojection is exactly the encoding of the function-space subprojection applied to the decoding of w.

Proof. This is the elementwise form of the defining threefold composite. ■

Theorem (`subU.subApprox_fix_of_fix`). If w is fixed by the universal subprojection, then its decoded function is fixed by the function-space subprojection.

Proof. Decode the fixed-point equation and use that decoding after encoding is the identity. ■

Theorem (`subU.fix_of_subApprox_fix`). If a function-space element is fixed by the function-space subprojection, then its encoding is fixed by the universal subprojection.

Proof. Expand the universal subprojection, cancel decoding after encoding, and use the given fixed-point equation. ■

Definition (`subU.fixIso`). The fixed points of the universal subprojection are order-isomorphic to the fixed points of the function-space subprojection, by decoding in one direction and encoding in the other.

Definition (`subU.fixIsoSubFixed`). The fixed points of the universal subprojection are order-isomorphic to the approximable self-maps f satisfying $\mathrm{sub}(f) = f$.

Theorem (`subU.isRetraction_conjArrow`). Conjugating any retraction of the function-space domain by the encoding and decoding maps produces a retraction of U.

Proof. In the square of the conjugated map, the middle decoding–encoding pair cancels and the repeated retraction collapses by idempotence. ■

Theorem (`subU.le_idMap_conjArrow`). If a function-space endomap lies below the identity, then its conjugate on U also lies below the identity.

Proof. Monotonicity of composition bounds the conjugate by encoding after decoding, which itself lies below the identity on U. ■

Theorem (`subU.isProjection_conjArrow`). Conjugating a function-space projection by the encoding and decoding maps produces a projection of U.

Proof. The conjugate is a retraction by the preceding idempotence result and lies below the identity by the preceding order result. ■

Theorem (`subU.isProjection`). The universal subprojection is a projection.

Proof. The function-space subprojection is a projection, and the universal subprojection is its conjugate under encoding and decoding. ■

Theorem (`subU.isFinitary`). The universal subprojection is finitary.

Proof. Its fixed-point domain is order-isomorphic to that of the finitary function-space subprojection, hence to an effectively given domain. ■

Theorem (`subU.isFinitaryProjection`). The universal subprojection is a finitary projection.

Proof. It is both a projection and finitary by the two preceding results. ■

4.9.75 Infinite product on U

This peer transports the dependent-product projection from the function-space domain to the universal domain and proves that the transported map is again a finitary projection.

Definition (`piU`). For a code assignment d, the universal dependent-product map decodes an element of U as a function, applies the dependent-product projection there, and encodes the result back into U.

Theorem (`toElementMap.piU`). The value of the universal dependent-product map at w is the encoding of the function-space dependent-product projection applied to the decoding of w.

Proof. This is the elementwise form of the defining composite. ■

Theorem (`piD.fix_of_piU_fix`). If w is fixed by the universal dependent-product map, then its decoding is fixed by the function-space dependent-product projection.

Proof. Decode the fixed-point equation and cancel decoding after encoding. ■

Theorem (`piU.fix_of_piD_fix`). If a function-space element is fixed by the dependent-product projection, then its encoding is fixed by the universal dependent-product map.

Proof. Expand the transported map, cancel decoding after encoding, and apply the assumed fixed-point equation. ■

Definition (`piU.FixIso`). Decoding and encoding give an order isomorphism between the fixed points of the universal dependent-product map and those of the function-space dependent-product projection.

Theorem (`isFinitary.piU_of_isFinitary_piD`). If the function-space dependent-product projection is finitary, then the universal dependent-product map is finitary.

Proof. Their fixed-point domains are order-isomorphic, so an effective presentation of the former transfers to the latter. ■

Theorem (`isFinitary.piU_of_formula`). If membership in the image of the function-space dependent-product projection has the finite self-related-neighbourhood characterization, then the universal dependent-product map is finitary.

Proof. The characterization makes the function-space map a finitary projection; finitarity then transfers across the fixed-point order isomorphism. ■

Theorem (`isProjection.piU`). The universal dependent-product map is a projection.

Proof. The function-space dependent-product map is a projection, and conjugation by the universal encoding and decoding maps preserves projections. ■

Theorem (`isFinitaryProjection.piU`). The universal dependent-product map is a finitary projection.

Proof. It is a projection by conjugation, and it is finitary because the function-space dependent-product projection is finitary. ■

4.9.76 Exercise 8.27 — infinite cartesian products

(Suggested by James Donahue.)

Finite cartesian products of domains are formed by the $D_0 \times D_1$-construct we have used so often. The problem is to define — computably — some *infinite* cartesian products. In particular, as applied to the universal domain U, the combinator `sub` is to be regarded as a finitary projection of U whose fixed points are exactly *all* the finitary projections. A map

$$d = \mathrm{sub} \circ d \circ \mathrm{sub}$$

can be regarded as a *polymorphic type* (because, whenever t is a finitary projection (= type), then so is $d(t)$). The *continuous product* of *all* these types would be the domain of all approximable functions x such that

$$x(t) = d(t)(x(t))$$

for all types t. (Why does this equation mean that x is in the product?) Define Π as a combinator by

$$\Pi = \lambda d\, \lambda x\, \lambda t.\, \mathrm{sub}(d(\mathrm{sub}(t)))(x(\mathrm{sub}(t))).$$

Show that for d a polymorphic type, $\Pi(d)$ is a type. (Hint: It is easy to check that $\Pi(d)$ is a projection; the problem is to show it is *finitary*.)

The development is with the Infinite product on U peer.

Theorem (`example_827`). The infinite cartesian product of a projection is again a finitary projection.

Proof. By assembling the peer lemmas named in the packaging module. ■

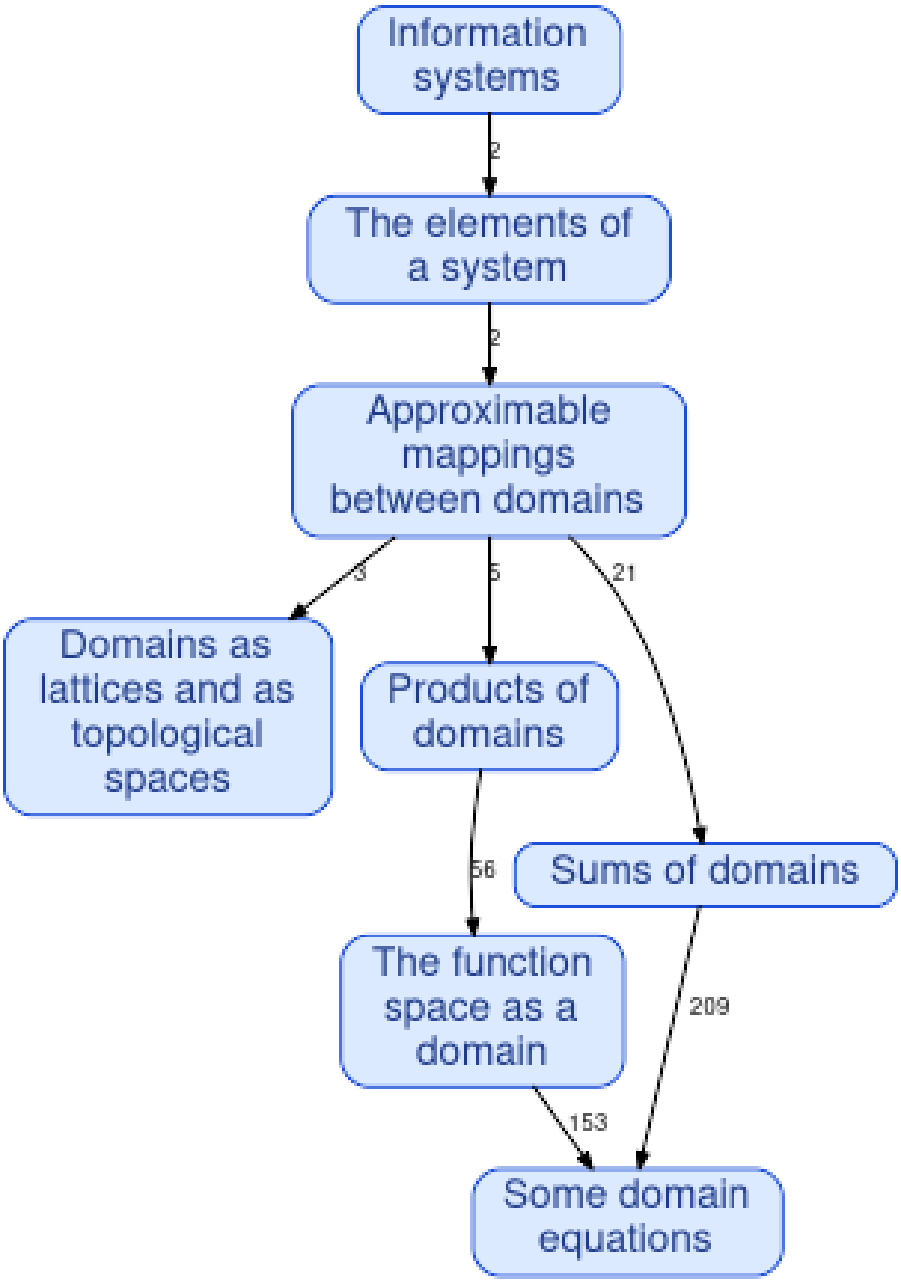

Figure 54: Diagram 19

5.1 Introduction

The purpose of the theory of domains is to give models for spaces on which to define computable functions. The kinds of spaces needed for denotational semantics involve not only spaces of higher type (e.g. function spaces) but also spaces defined recursively (e.g. reflexive domains). Also required are many special domain constructs (or functors) in order to create the desired structures. There are several choices of a suitable category of domains, but the basic one which has the simplest properties is the one sometimes called *consistently complete algebraic* cpo*'s*. This category of domains is studied in this paper from a new, and it is to be hoped, simpler point of view incorporating the approaches of many authors into a unified presentation. Briefly, the domains of elements are represented set theoretically with the aid of structures called *information systems*. These systems are very familiar from mathematical logic, and their use seems to accord well with intuition. Many things that were done previously axiomatically can now be proved in a straightforward way as theorems. The present paper discusses many examples in an informal way that should serve as an introduction to the subject.

1. Introduction. I would like to begin with some personal remarks. When I think of the number of headaches I have caused people in Computer Science who have tried to figure out the mathematical details of the Theory of Domains, I have to cringe. The difficulty in the presentation of the subject is in justifying the level of abstraction used in comparison with the payoff: too often the effort needed for understanding the abstractions does not seem worth the trouble—especially if the notions are unfamiliar or excessively general.

For example, Category Theory, which is much used in discussions of the Theory of Domains, seems far too abstract to many people. On the other hand, Automata Theory—which has often benefited from some use of Category Theory—is quite abstract and, in many aspects perhaps, quite useless, but the level of abstraction is fairly low and the reasons for the definitions are usually evident. Thus, the subject has become by now a standard topic even for undergraduate courses. I believe that Michael Rabin and I had much to do with influencing the subsequent development of the theory by formulating some years ago some basic concepts (many previously known) in a way that made sense to anyone who had been exposed to a little Abstract Algebra, Logic and Set Theory. This expository part of our paper did not require originality, but rather a certain frame of mind and a certain style of writing to put the ideas and problems in sharp relief. (The original paper is [**?**]; see the excellent historical review of the subject in [**?**].)

Domain Theory has fared less well. I feel I made a mistake in 1969 in using Lattice Theory as a mode of presentation—a mistake as far as Computer Science is concerned. Lattices are very familiar to logicians and those interested in Universal Algebra, and I liked very much the structures I found. But it takes some time to learn the special terminology and to become comfortable with the necessary examples. Indeed, without a stock of examples, it is impossible to have sufficient intuition for making the required constructions. True, some people took to the approach, and the lattice-theoretic definitions were simple enough to motivate. But a much

greater percentage of people I came in contact with found the large number of things to learn a definite roadblock to understanding. And the Lattice Theory was only partly standard, since this approach to the theory has to employ complete lattices and topological notions in order to explain *limits* and *continuity* adequately. In fact, Topology of a rather mathematically simple set-theoretical kind could have been used as the whole foundation much as in [1], but that kind of mathematics seems even less attractive to computer scientists. Again, it is a matter of background, I think, and it is unreasonable to expect people to know everything. Nevertheless, the lattice-theoretic approach has great consistency and coherence; it has been carried out in full detail in [**?**], which also gives the topological connections. That book contains a large number of references to the mathematical literature to show the connections of the theory to many other

topics. What we had to miss out there is a clear hook-up with computability theory, owing simply to a lack of space and time to be able to cover everything.

In [2], I tried out another, different presentation (which is also explained in [3].) However, I have found that the use of *neighborhood systems* causes confusion in people not used to thinking in terms of sets of sets of sets of sets . . . , even though the set theory required is quite simple. My purpose in the present lecture, then, is to go back once more to the very beginning to try out another plan for making the story easy and natural. The notion to be used I call an *information system*. This is a "static" notion appropriate to bodies of information about coherent groups of elements. The "dynamic" ideas enter in the ways different systems can be related and in the semantical definitions about meanings of programming language constructs. (For discussions of semantical definitions see [**?**], [**?**], and [**?**].) Neighborhood systems are, in a precise sense, equivalent to information systems, but there seems to be an interesting trade-off between what properties of structures are *axiomatized* and what are *implicit* in the form of the structure. Perhaps, despite their simplicity, neighborhoods leave too much implicit, too much to be extracted by definition; information systems, on the other hand, do seem to be more flexible in doing several of the important constructions. It all comes down to just where one imposes the closure conditions on the structures. I have a feeling that I now have found just about the right mix of axioms *vs.* definitions.

Another word about Category Theory: I actually feel that it is particularly significant and important for the theory and for the whole area of semantics. But it must be approached with great caution, for the sheer number of definitions and axioms can try the most patient reader. It seems to me to be especially necessary in discussing applications of abstract mathematical ideas to keep the motivation strongly in mind. This is often hard to do if the categories get too thick, but of course it all depends on the writer. Category Theory is especially useful in stating *general* properties of structures and in *characterizing* constructions uniquely; however, there often is a problem actually justifying the *existence* of certain constructions, and a direct approach can be quicker than quoting lots of theorems. But, man cannot live by construction alone: theorems have to be proved in order to get the proper value out of the work. Domain Theory must also be convenient for demonstrating the soundness of various proof rules for properties of recursively defined objects and recursively defined domains, and I think that Category Theory can be helpful here. A step in the right direction has been made in the LCF system (see [**?**]), which, however, does not take advantage of general Category Theory; but the whole area needs much more development in my opinion.

The main purpose of the Theory of Domains in Denotational Semantics, as I see it, is to give a mathematical model of a system of *types*—including function-space types—and to explain

a notion of computability with respect to these types. There are many possible theories of types, but the construction of domains is meant to justify recursive definitions at all types, and—most essentially—to justify recursive definitions of types. Pursuing these goals has certain consequences, as we shall see. The model presented here is only one approach, and some comparisons with other methods will be made in Section 8. Again some help from Category Theory would be welcome in comparing the different kinds of modelling.

One benefit of Domain Theory is that it is possible to make sense of types containing *infinite* elements. The cost required seems to be that the domains therefore have to contain *partial* elements as well as *total* elements. And this is where the lattice-theoretic definitions entered in the earlier presentations: the partial ordering with relations like $x \sqsubseteq y$ was used to express the fact that the element x was "less defined" (i.e. more partial) than y but "contained in" y. The relation $\sqsubseteq$, however, must be subjected to many axioms to have a theory suitable to the desired applications. Instead of such a big group of axioms, I wish to put forward here a construction where the "skeleton" (or better: "backbone") of a domain is introduced by just a few axioms. Then the domain itself is defined as a certain construct from the backbone in order to define

the appropriate notion of element. There are several advantages I can see to the new approach:

- Simple definitions of the basic concepts can be given.
- Detailed properties are proved as theorems rather than assumed as axioms.
- Emphasis can be given to the constructive nature of the definitions.
- Domains can be made more visible.
- The theory of domains is made more available for applications, because it is easier to produce the needed complex domains.

It is to be hoped that the reader can judge the validity of these claims from the perhaps too brief exposition to follow.

5.2 Information systems

<!DOCTYPE svg PUBLIC "-//W3C//DTD SVG 1.1//EN" "http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd">

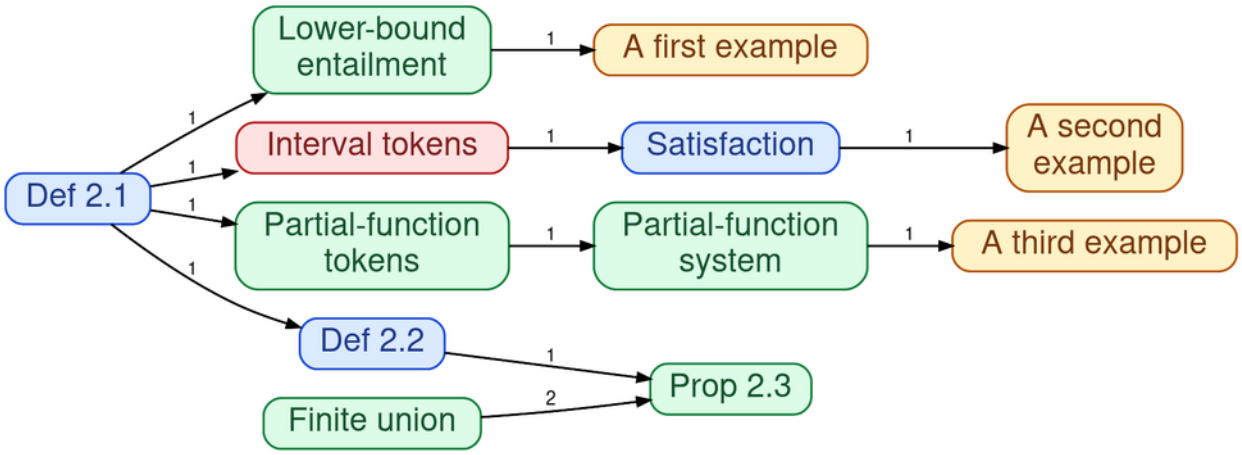

Figure 55: Diagram 20

5.2.1 Introduction

2. Information systems. Intuitively, an information system is a set of "propositions" that can be made about "possible elements" of the desired domain. We will assume that sufficiently many propositions have been supplied to distinguish between distinct elements; as a consequence, an element can be constructed abstractly as the set of all the propositions that are true of it. Partial elements have "small" sets; while total elements have "large" sets (even: maximal). To make this somewhat rough idea precise, we have to explain—by a suitable, but small choice of axioms—how the collection of all propositions relevant to the domain hangs together, or better, is structured as a set of abstract propositions. Fortunately, the axioms for this structure are very simple and familiar, which is a great help in making up examples.

5.2.2 Definition 2.1

DEFINITION 2.1. An *information system* is a structure

$$(D, \Delta, \mathrm{Con}, \vdash),$$

where D is a set (the set of data objects or propositions), where Δ is a distinguished member of D (the least informative member), where Con is a set of finite subsets of D (the consistent sets of objects), and where $\vdash$ is a binary relation between members of Con and members of D (the

entailment relation for objects). Concerning Con, the following axioms must be satisfied for all finite subsets $u, v \subseteq D$:

(i) $u \in \mathrm{Con}$, whenever $u \subseteq v \in \mathrm{Con}$;

(ii) $\{X\} \in \mathrm{Con}$, whenever $X \in D$; and

(iii) $u \cup \{X\} \in \mathrm{Con}$, whenever $u \vdash X$.

Concerning $\vdash$, the following axioms must be satisfied for all $u, v \in \mathrm{Con}$, and all $X \in D$:

(iv) $u \vdash \Delta$;

(v) $u \vdash X$, whenever $X \in u$; and

(vi) if $v \vdash Y$ for all $Y \in u$ and $u \vdash X$, then $v \vdash X$.

In words we may say of Con that, as a set of sets, (i) it is closed under subsets, (ii) it contains all singletons, and (iii) adjunction of an entailed object to a consistent set preserves consistency. Concerning $\vdash$, which should be viewed as a "multiary" relation, we may say that (iv) Δ is entailed by anything, (v) $\vdash$ is reflexive, and (vi) $\vdash$ is transitive. (The last two properties are both expressed in a way appropriate to a multiary relation on members of D.) ?

The best advice is to think of the members of D as consisting of finite data objects, some of which are more informative than others. The word "finite" should be taken here in the sense of "fully circumscribed"—as regards what is given in **A** these data objects can be comprehended in "one step." It is of course possible to introduce information systems where the data objects are infinite sets, but relative to **A** they are finite as data objects.

The member that provides zero information is Δ. Data objects are intended to give information about possible elements of the domain to be constructed, so if we were to use Δ alone, we would be describing the least defined element usually written as $\perp$.

Not just any combination of data objects will describe a possible element, however; hence, the need for the notion of consistency. If $u \in \mathrm{Con}$ is false, then the "propositions" in u cannot all be applied to the same element at the same time. Finally we have to agree that, in general, the propositions to be allowed are rarely mutually independent. It follows that an entailment relation must be imposed to record the dependencies that do hold among the propositions. With these informal understandings, the axioms chosen should all be self-evident.

Definition (`InfoSys`). An information system on a carrier α consists of a distinguished least-informative datum $\Delta \in \alpha$, a collection Con of finite subsets of α (the consistent sets), and an entailment relation $\vdash$ between consistent sets and data, subject to Scott's six axioms: Con is downward closed under subsets and contains every singleton; if $u \vdash X$ then $u \cup \{X\}$ is consistent; every consistent u entails Δ;

membership in u yields entailment from u; and entailment is transitive in the multiary sense—if v entails every member of u and $u \vdash X$, then $v \vdash X$. Here Δ is the bottom datum, Con and $\vdash$ are the consistency and entailment fields, and the six named axioms match clauses (i)–(vi) of Definition 2.1.

5.2.3 Lower-bound entailment

Definition (`lowerBoundEnt`). For finite sets u of natural numbers and a natural number m, write u lowerBoundEnt m when either $m = 0$ or some $n \in u$ satisfies $m \leq n$. Reading each n as the proposition $n \leq x$, this is the entailment relation for Scott's first example: the empty-information datum 0 is always entailed, and otherwise a lower bound is entailed when some listed bound already meets or exceeds it.

lowerBoundEnt.lean

```
module

public import DomainTheory.InformationSystems.InformationSystems.InfoSys

@[expose] public section

namespace DomainTheory.InformationSystems

def lowerBoundEnt (u : Finset ℕ) (m : ℕ) : Prop :=
  m = 0 ∨ ∃ n ∈ u, m ≤ n

end DomainTheory.InformationSystems
```

5.2.4 A first example

A first example. Suppose we let D be the set of non-negative integers, where we think of an integer n as an abbreviation of the proposition $n \leq x$. Here x is a yet-to-be-determined element, about which one proposition gives only a little information. We can identify Δ with 0, and take Con to be the set of all finite subsets of D. The entailment relation can be defined formally in the way suggested by the intuitive reading of the data objects:

$$\{n_0, \ldots, n_{k-1}\} \vdash m \quad \text{iff either } m = 0 \text{ or } m \leq n_i \text{ for some } i < k.$$

(Remember to think of the same possible x on both sides of the $\vdash$.) That $\vdash$ is an entailment relation in the sense of our axioms is clear. ?

Definition (`a_first_example`). Scott's first example is the information system on the natural numbers with least-informative datum 0, every finite subset consistent, and entailment given by lower-bound entailment: a finite u entails m when $m = 0$ or some $n \in u$ satisfies $m \leq n$. The six information-system axioms hold for this choice of consistency and entailment.

a_first_example.lean

```
module

public import DomainTheory.InformationSystems.InformationSystems.InfoSys
public import DomainTheory.InformationSystems.InformationSystems.lowerBoundEnt

@[expose] public section

        exact Or.inl (Nat.le_zero.mp hcn)
      · exact Or.inr ⟨k, hk, le_trans hcn hnk⟩

end DomainTheory.InformationSystems
```

5.2.5 Interval tokens

Definition (`Token`). The data objects for Scott's second example are tokens of two kinds: a least-informative datum $\bot$, and open intervals (n, m) of natural numbers with $n < m$, standing for the proposition $n < x < m$.

Definition (`Token.instDecidableEq`). Equality of tokens is decidable: the bottom token equals only itself, and two intervals are equal precisely when they share the same endpoints.

`Token.lean`

```
module

public import Mathlib.Algebra.Order.Field.Rat
public import Mathlib.Tactic.Linarith
```

```
public import Mathlib.Tactic.NormNum
public import DomainTheory.InformationSystems.InformationSystems.InfoSys

@[expose] public section

namespace DomainTheory.InformationSystems

inductive Token : Type where
  | bot
  | interval (lo hi : ℕ) (hlt : lo < hi)

        rfl)
    else
      isFalse (by
        intro hEq
        injection hEq with hn hm
        exact h ⟨hn, hm⟩)

end Token

end DomainTheory.InformationSystems
```

5.2.6 Satisfaction

Definition (`Sat`). A rational x satisfies the bottom token, and satisfies an interval token (n, m) precisely when $n < x < m$.

Theorem (`sat_midpoint`). The midpoint of an open interval of natural numbers satisfies that interval token.

Proof. The midpoint lies strictly between the endpoints by the ordering of the rationals. ?

Theorem (`sat_sing`). Every token is satisfied by some rational: the bottom token by 0, and each interval by its midpoint.

Proof. The bottom case is immediate; the interval case is the midpoint theorem. ?

Definition (`ofSatisfaction`). Given a satisfaction relation between points and tokens with a least-informative token always satisfied and every token satisfied by some point, form an information system whose consistent sets are those realized by a common point and whose entailment holds when every point realizing the antecedents realizes the conclusion. The six information-system axioms follow from these reading of consistency and entailment.

    intro y hy
    exact (hvu y hy).2 p hp

end DomainTheory.InformationSystems
```

5.2.7 A second example

A second example. The first example is possibly misleading because all (finite) sets of data objects were allowed to be consistent. The example can be modified in a natural way so this is not so; of course, quite a different system will be obtained. The idea is to let D be the set of all pairs (n, m) of integers with $n < m$, where such a pair stands now for the proposition $n < x < m$. Clearly the two data objects $(0, 2)$ and $(3, 7)$ taken together are inconsistent. (Why?)

Oh, I see, I have left out Δ from D; we must therefore include the somewhat artificial pair $(0, \infty)$ with the obvious interpretation. When I say "obvious interpretation" here I mean that $u \in \mathrm{Con}$ can be defined by saying that there must be an integer satisfying all the "propositions" in u. Further, $u \vdash X$ can be defined by saying that whenever an integer satisfies all the propositions in u, then it must satisfy X. The notion of "satisfy" really should be obvious from the intuitive reading given to the data objects, and the reader can verify easily that all the axioms hold for this example of an information system. ?

Definition (`a_second_example`). Scott's second example is the information system on interval tokens obtained from rational satisfaction via the satisfaction construction: the least-informative datum is the bottom token, consistency and entailment are those induced by whether a common rational realizes the tokens, and the six axioms hold by that construction together with the fact that every token is satisfied by some rational.

`a_second_example.lean`

```
module

public import DomainTheory.InformationSystems.InformationSystems.Sat

@[expose] public section

namespace DomainTheory.InformationSystems

def a_second_example : InfoSys Token :=
  ofSatisfaction Sat Token.bot (fun _ => trivial) sat_sing

end DomainTheory.InformationSystems
```

5.2.8 Partial-function tokens

Definition (`PartialFunToken`). For sets A and B, a partial-function token is either a least-informative datum $\bot$, or a pair (a, b) with $a \in A$ and $b \in B$, standing for the proposition that a yet-to-be-determined function sends a to b. Equality of such tokens is decidable.

PartialFunToken.lean

```
module

public import DomainTheory.InformationSystems.InformationSystems.InfoSys

@[expose] public section

namespace DomainTheory.InformationSystems

inductive PartialFunToken (A B : Type*) where
  | bot
  | pair (a : A) (b : B)
  deriving DecidableEq

end DomainTheory.InformationSystems
```

5.2.9 Partial-function system

Definition (`PartialFunConsistent`). A finite set u of partial-function tokens is consistent when it does not assign two distinct values to the same argument: whenever (a, b) and (a, b') both lie in u, one has $b = b'$.

Definition (`PartialFunEnt`). A consistent finite set u of partial-function tokens entails a token X precisely when X is the bottom token or X already belongs to u.

Theorem (`consistent_empty`). The empty set of partial-function tokens is consistent.

Proof. No pair belongs to the empty set, so the functional condition holds vacuously. ?

Theorem (`consistent_subset`). Consistency is downward closed under subsets.

Proof. Any conflicting pair in a subset would already conflict in the larger set. ?

Theorem (`consistent_singleton`). Every singleton of partial-function tokens is consistent.

Proof. The bottom token contributes no pairs; a single pair cannot conflict with a distinct value for the same argument. ?

Theorem (`consistent_insert_bot`). Inserting the bottom token into a consistent set preserves consistency.

Proof. Bottom is not a pair, so membership of pairs is unchanged. ?

Theorem (`consistent_insert_mem`). Inserting a token already present in a consistent set preserves consistency.

Proof. The insert does not enlarge the set. ?

Definition (`partialFunctionSystem`). For decidable A and B, the partial-function information system on partial-function tokens has least-informative datum $\bot$, consistency given by partial-function consistency, and entailment given by partial-function entailment. The six information-system axioms hold by the consistency lemmas above together with the minimal reading of entailment.

5.2.10 A third example

A third example. Let A and B be two fixed sets, and let D as a set consist of the ordered pairs (a, b), with $a \in A$ and $b \in B$, plus the extra object Δ. Here the "information" contained in (a, b) is that a is mapped to b by a yet-to-be-determined function. With this thought in mind, we will know that a finite set of data objects is consistent just in case it is possible that they can all belong to the same function. Formally, we can assert:

$$\{(a_0, b_0), \ldots, (a_{k-1}, b_{k-1})\} \in \mathrm{Con} \text{ iff for all } i, j < k \text{ whenever } a_i = a_j, \text{ then } b_i = b_j.$$

It is something of a bother having to throw in Δ in this case, but all we have to say is that if u is consistent under the above rule, then so also will $u \cup \{\Delta\}$; and these are the only consistent sets of data objects for this example. Perhaps it would make more sense to use $\{(a, b)\}$ in place of the simpler (a, b), and then we could set $\Delta = \emptyset$ more naturally. From this point of view we can regard each data object as a (very small!) fragment of the graph of a function; the consistent sets then point to larger fragments of graphs.

The definition of the entailment relation is the minimal one:

$$u \vdash X \text{ iff either } X = \Delta \text{ or } X \in u.$$

These examples show that sometimes the main part of the structure is in Con, sometimes it is in $\vdash$, and sometimes it is in the interplay between the two notions. The object Δ is not in itself very important, but it is sometimes useful to have an object there that can always be counted upon to act in the same way in every system. ?

Already in formulating the axiom about the transitivity of $\vdash$ a relation between sets in Con was suggested; we now make this official.

Definition (`a_third_example`). Scott's third example is the partial-function information system on partial-function tokens for decidable sets A and B: least-informative datum $\bot$, consistency the functional condition on pairs, and minimal entailment. It is exactly the partial-function system for A and B.

5.2.11 Definition 2.2

DEFINITION 2.2. *For $u, v \in \mathrm{Con}$ we write $u \vdash v$ to mean that $u \vdash X$ for all $X \in v$.* ?

Definition (`InfoSys.EntSet`). In an information system, write u EntSet v when u entails every member of the finite set v. This is Scott's multiary reading $u \vdash v$ of Definition 2.2 (stated for arbitrary finite u, v on the carrier).

Theorem (`InfoSys.EntSet.empty`). Every finite set entails the empty set of data.

Proof. There is no member of the empty set to entail. ?

Theorem (`InfoSys.EntSet.singleton`). Entailing a singleton $\{X\}$ is equivalent to entailing X.

Proof. Both directions unwind the definition of multiary entailment on a one-element set. ?

Theorem (`InfoSys.EntSet.bot`). The empty set of data entails the singleton of the least-informative datum.

Proof. Entailment of the bottom datum from the empty consistent set. ?

Theorem (`InfoSys.EntSet.union_mem`). If a consistent set u entails every member of a finite set v, then the finite union $u \cup' v$ is consistent.

Proof. Induct on v, closing under insert via entailment and the consistency axiom for entailed data; the empty case is u itself. ?

Theorem (`InfoSys.EntSet.refl`). Every consistent set entails itself.

Proof. Membership yields entailment. ?

Theorem (`InfoSys.EntSet.trans`). Multiary entailment is transitive: if u entails v and v entails w, with u and v consistent, then u entails w.

Proof. For each member of w, combine the multiary hypotheses with transitivity of unary entailment. ?

Theorem (`InfoSys.EntSet.mono`). Multiary entailment is monotone in the antecedents and antitone in the consequents: enlarging a consistent antecedent set and shrinking the entailed set preserves entailment.

Proof. Reduce to unary entailment from the smaller antecedent, then transfer along the inclusion by reflexivity and transitivity. ?

Theorem (`InfoSys.EntSet.union`). If u entails each of two finite sets, then u entails their finite union.

Proof. Membership in a finite union is membership in one of the arguments. ?

5.2.12 Finite union

Theorem (`Constructive.insert_comm'`). Inserting two elements into a finite set may be done in either order.

Proof. Membership in a double insert is disjunction of three alternatives; reordering the inserts merely reorders those alternatives. ?

Definition (`Constructive.instLeftCommutativeInsert`). Insert is left-commutative on finite sets, so multiset folds over insert are well-defined independently of order.

Definition (`Constructive.funion`). The finite union $u \cup' v$ is the result of inserting every member

of v into u, via a multiset fold. The infix $\cup'$ denotes this operation.

Definition (`Constructive.decidableEq_finset`). Equality of finite sets is decided by mutual inclusion.

Theorem (`Constructive.decidableEq_finset.eq_of_subset`). Mutual inclusion yields equality of finite sets.

Proof. Antisymmetry of the subset order. ?

Theorem (`Constructive.decidableEq_finset.false_of_ne`). A set is not unequal to itself under the mutual-inclusion test.

Proof. Reflexivity of $\subseteq$. ?

Theorem (`Constructive.funion.mem_foldr_insert`). An element lies in a fold of insert over a multiset into a finite set precisely when it lies in the seed set or in the multiset.

Proof. Induction on the multiset, using the membership rule for insert at each cons step. ?

Theorem (`Constructive.funion.mem`). Membership in a finite union is membership in either argument.

Proof. Finite union is a fold of insert, so the fold membership lemma applies. ?

Theorem (`Constructive.funion.empty_right`). Finite union with the empty set on the right is the left argument.

Proof. Membership reduces by the membership lemma. ?

Theorem (`Constructive.funion.subset_left`). Each argument of a finite union is a subset of the union (left).

Proof. Membership in the left argument yields membership in the union. ?

Theorem (`Constructive.funion.subset_right`). Each argument of a finite union is a subset of the union (right).

Proof. Membership in the right argument yields membership in the union. ?

Theorem (`Constructive.funion.subset_iff`). A finite union is a subset of w precisely when both arguments are.

Proof. Both directions use the membership and subset lemmas for finite union. ?

Theorem (`Constructive.funion.coe`). Coercion of a finite union to a set is the set-theoretic union of the coercions.

Proof. Membership agrees by the membership lemma. ?

Theorem (`Constructive.funion.insert`). Finite union commutes past insert on the right: $u \cup' \mathrm{insert}\, a\, t = \mathrm{insert}\, a\, (u \cup' t)$.

Proof. Compare membership on both sides via the membership lemma and the insert rule. ?

Theorem (`Constructive.funion.singleton_eq_insert`). Finite union of a singleton with a finite set is the corresponding insert.

Proof. Membership on either side is the same by the membership and insert characterizations. ?

Theorem (`Constructive.funion.comm`). Finite union is commutative: $a \cup' b = b \cup' a$.

Proof. Compare membership on both sides via the membership lemma for finite union. ?

Theorem (`Constructive.funion.assoc`). Finite union is associative: $(a \cup' b) \cup' c = a \cup' (b \cup' c)$.

Proof. Compare membership on both sides, splitting each disjunction according to the membership lemma. ?

Theorem (`Constructive.funion.left_comm`). Finite union is left-commutative: $a \cup' (b \cup' c) = b \cup' (a \cup' c)$.

Proof. Compare membership on both sides via the membership lemma. ?

Theorem (`Constructive.funion.self`). Finite union is idempotent: $a \cup' a = a$.

Proof. Compare membership on both sides via the membership lemma. ?

5.2.13 Proposition 2.3

PROPOSITION 2.3. *For all* $u, v, w, u', v' \in \mathrm{Con}$*, we have:*

(i) $\emptyset \vdash \{\Delta\}$;

(ii) $u \vdash v$ implies $u \cup v \in \mathrm{Con}$;

(iii) $u \vdash u$;

(iv) $u \vdash v$ and $v \vdash w$ imply $u \vdash w$;

(v) $u' \supseteq u$, $u \vdash v$, and $v \supseteq v'$ imply $u' \vdash v'$; and

(vi) $u \vdash v$ and $u \vdash v'$ imply $u \vdash v \cup v'$.

Proof. Obvious. ?

Remark. It is not worth formulating a formal result at this point, but it should be clear that the properties in 2.3 could have been used as axioms. That is to say, we could have taken $\vdash$ as a binary relation on the set Con, used 2.1 (i)–(ii) and 2.3 (i)–(vi) as axioms. (Actually, 2.3(ii) is redundant.) The old-style entailment relation would then be definable by:

$$u \vdash X \quad \text{iff} \quad u \vdash \{X\}.$$

The previous axioms in 2.1 are then easily proved from the new ones. ?

Some notation. As it is not always clear what structure is meant if we refer to a domain simply by naming its underlying set of data objects, it will be better if we use a letter to refer to an information system as a whole. We shall therefore write:

$$\mathbf{A} = (D_{\mathbf{A}}, \Delta_{\mathbf{A}}, \mathrm{Con}_{\mathbf{A}}, \vdash_{\mathbf{A}}),$$

and say that $\mathbf{A}$ is an information system—with its parts as indicated. For a more informal discussion, the notation without subscripts can suffice, but there can be problems when several different systems are involved. ?

So much for the definition of what a system is as a mathematical structure. The next question is: What is it good for? More precisely, if information systems are the backbones of domains, then where are the elements? That is the topic of the next section.

Theorem (`proposition_2_3`). For consistent finite sets, multiary entailment satisfies: the empty set entails $\{\Delta\}$; entailment of v from u yields consistency of $u \cup' v$; reflexivity; transitivity; monotonicity in antecedents and antitonicity in consequents; and closure under finite unions of consequents.

Proof. Assemble the six multiary-entailment library facts for bottom, consistency of unions, reflexivity, transitivity, monotonicity, and union of consequents. ?

5.3 The elements of a system

<!DOCTYPE svg PUBLIC “-//W3C//DTD SVG 1.1//EN” “http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd”>

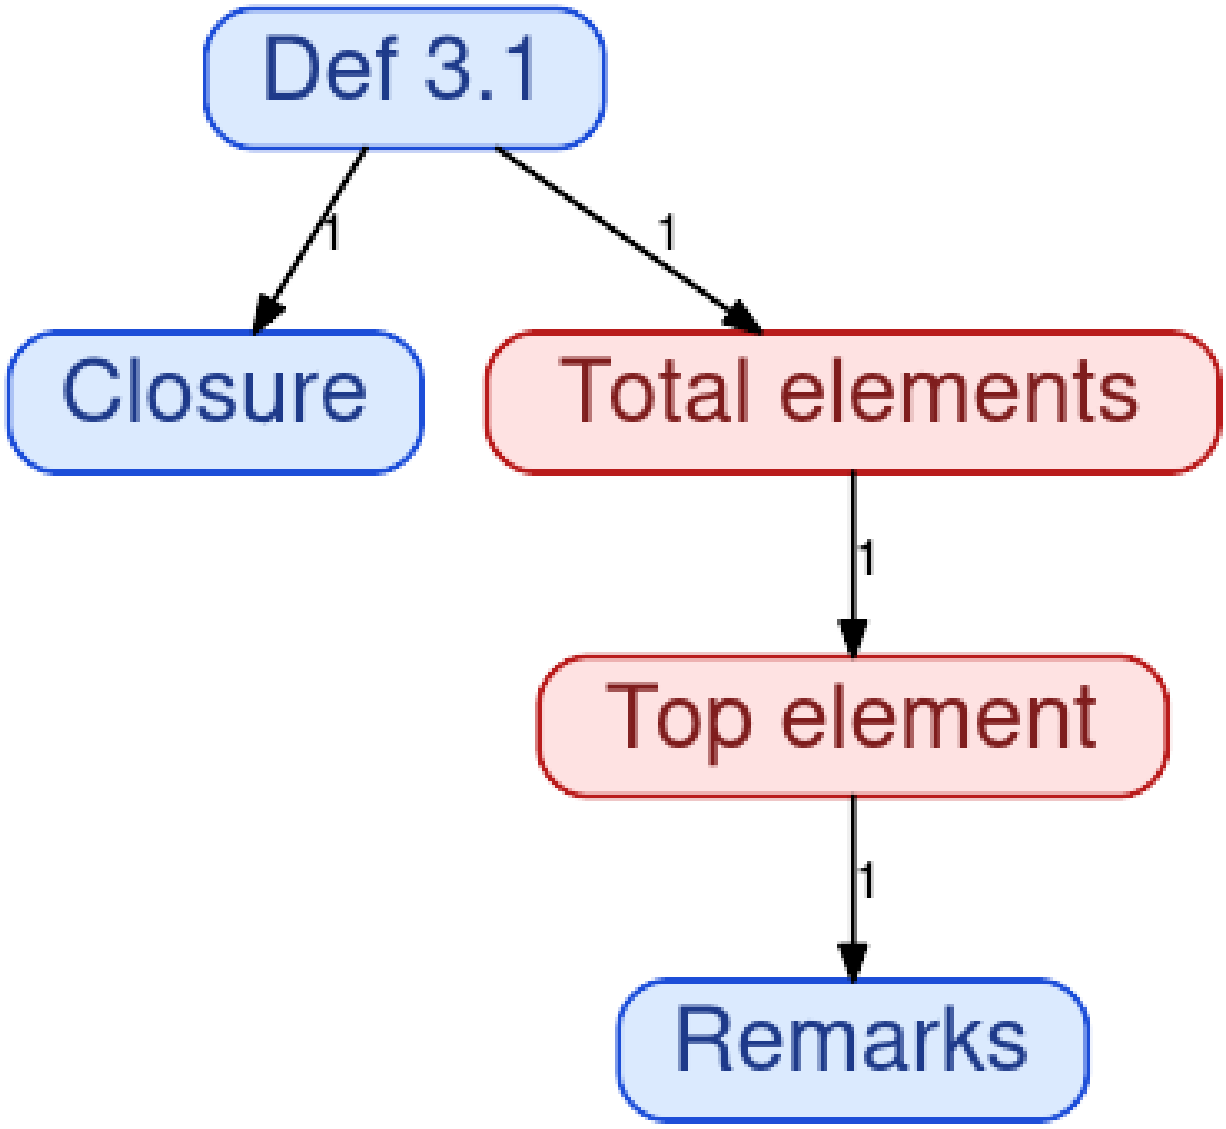

Figure 56: Diagram 21

5.3.1 Introduction

Let $\mathbf{A}$ be an information system, and suppose we already had a concept of being an element of $\mathbf{A}$. The data objects are meant to be propositions about elements, so if X is in $D_{\mathbf{A}}$ and if x is an element, then we can be expected to know what it means to say that X is true of x. Since all we are given is the set of data objects $D_{\mathbf{A}}$, we have to assume that it contains enough objects to distinguish between distinct elements. (If there were not enough of them, we would have to change the set $D_{\mathbf{A}}$.) Formally, we can write of two elements x and y:

$$x = y \quad \text{iff all } X \in D_{\mathbf{A}} \text{ which are true of } x \text{ are also true of } y, \text{ and conversely.}$$

If this principle is accepted, then the elements can be *identified* with the sets of propositions true of

them; formally we can assert:

$$x = \{X \in D_{\mathbf{A}} \mid X \text{ is true of } x\}.$$

There can be no confusion injected here in identifying elements that ought to be distinct, since we are assuming that there are enough data objects in the system. If for some reason we felt we ought to have more of them to distinguish between more elements, then we would have to pass to a larger and *different* information system. By agreement, then, the above equation is a tautology.

So, for the sake of simplicity, elements can be taken to be *sets* of data objects. But, we hasten to ask, which sets? The question is really: What are the properties of truth? The answers are well known, and, in fact, we have already used them in our examples in the last section. In words, the set of true propositions about a possible element must be (i) consistent in itself, and (ii) closed under entailment (or *deductively closed*, for short). Condition (i) is clear because we are talking about a *possible* element, not an impossible one. Condition (ii) is acceptable, because, by the very meaning of the word, entailment should be truth preserving. In addition, we are also saying the converse: *any* set having properties (i) and (ii) corresponds to a (partial) element. Here is the formal statement:

5.3.2 Definition 3.1

DEFINITION 3.1. The *elements* of the information system $\mathbf{A} = (D_{\mathbf{A}}, \Delta_{\mathbf{A}}, \mathrm{Con}_{\mathbf{A}}, \vdash_{\mathbf{A}})$ are those subsets x of $D_{\mathbf{A}}$ where:

(i) all finite subsets of x are in $\mathrm{Con}_{\mathbf{A}}$; and

(ii) whenever $u \subseteq x$ and $u \vdash_{\mathbf{A}} X$, then $X \in x$.

We write $x \in |\mathbf{A}|$ to mean x is an element of the system. This set of elements is the *domain* determined by the given system. An element that is not included in any strictly larger element in the domain is called a *total element*; the set of total elements is denoted by $\mathrm{Tot}_{\mathbf{A}}$. ?

Definition (`InfoSys.Element`). An element of an information system is a set of data that is finitely consistent—every finite subset lies in Con—and deductively closed: whenever a finite set of data from the carrier entails a further datum, that datum belongs to the carrier. The domain $|\mathbf{A}|$ is the collection of all such elements.

Theorem (`InfoSys.Element.ext`). Two elements are equal precisely when they have the same carrier.

Proof. An element is determined by its carrier together with the consistency and closure witnesses, which are propositions. ?

Theorem (`InfoSys.Element.le_refl`). Carrier inclusion is reflexive on elements.

Proof. Every set is a subset of itself. ?

Theorem (`InfoSys.Element.le_trans`). Carrier inclusion is transitive on elements.

Proof. Subset is transitive. ?

Theorem (`InfoSys.Element.le_antisymm`). Carrier inclusion is antisymmetric on elements.

Proof. Mutual inclusion of carriers yields equal carriers, hence equal elements. ?

Definition (`InfoSys.Element.instPartialOrder`). The domain of elements is partially ordered by inclusion of carriers.

5.3.6 Remarks

Remarks. Any subset of $D_{\mathbf{A}}$ satisfying 3.1 (i) can be called consistent, and every consistent set generates an element by closing it under entailment. Note, too, that every element contains $\Delta_{\mathbf{A}}$ as a member, because the least informative proposition is true of all elements. Moreover, every domain has a least element contained in all other elements. We call it $\bot_{\mathbf{A}}$ and write formally:

$$\bot_{\mathbf{A}} = \{X \in D_{\mathbf{A}} \mid \{\Delta_{\mathbf{A}}\} \vdash_{\mathbf{A}} X\}.$$

In the above we could just as well have used the empty set $\emptyset$ in place of $\{\Delta_{\mathbf{A}}\}$; and often we can write simply $\vdash_{\mathbf{A}} X$.

The element $\bot_{\mathbf{A}}$ is often called the *bottom* element of the domain. There need be no *top* or maximal element, $\top_{\mathbf{A}}$. Such an element is possible if, and only if, *all* finite subsets of $D_{\mathbf{A}}$ are consistent, in which case, as a set, $\top_{\mathbf{A}} = D_{\mathbf{A}}$. The possibility is not excluded—rather, it is not required. In case $\top_{\mathbf{A}}$ exists, it is the unique total element of the domain, and conversely. ?

Returning to our question of the balance between axiomatizaton and construction, what we have done is first to axiomatize the properties of $(D_{\mathbf{A}}, \Delta_{\mathbf{A}}, \mathrm{Con}_{\mathbf{A}}, \vdash_{\mathbf{A}})$, then to construct the domain $|\mathbf{A}|$ from this structure. The principal claimed advantages are that the axioms for consistency and entailment are already essentially familiar, and that the definition of elementhood is direct and natural from our understanding of the properties of truth.

The examples. Let us look again at the three examples of information systems of the last section. (1) In the first we see that the elements, by the formal definition, are either the finite sets $\{n \mid n \leq m\}$ or the whole set (i.e. $\top$). Intuitively, this corresponds to the fact that the chosen propositions only give *lower bounds* on a possible element; thus, no element is "finished" until it becomes infinite. (2) In the second example there is no top, and the elements are the sets of the form:

$$\{(n, q) \mid n \leq m \leq p \leq q\},$$

where $m \leq p$ are given, and where $q = \infty$ is allowed. The total elements here correspond to the (non-negative) integers, and the partial elements to situations where the lower and upper bounds have not come exactly together. (3) In the third example, the elements are just the graphs (i.e. sets of ordered pairs) of partial functions from A into B (with the object Δ adjoined to the graph). Total elements correspond to total functions (i.e. functions well defined on all of the set A). ?

The reader should be able to obtain some more examples of information systems from his own experience and should then consider what the corresponding domain is like. Examples are really quite easy to make up. Needless to say, Mathematical Logic provides a host of information systems, but logicians do not often consider the domains determined by the the systems they know to be worthy of study *in themselves*. In particular, it does not seem to be widely recognized that the domains obtained from information systems form a rich category, as we shall show later. The word "category" is definitely being used here in the precise technical sense of Category Theory, and the application of the notion is very appropriate since the category of domains has very good closure properties.

Theorem (`InfoSys.remark`). A top element—an element whose carrier is the whole set of data—exists if and only if every finite set of data is consistent.

Proof. This is the library comparison of universal carriers with all-consistency. ?

5.4 Domains as lattices and as topological spaces

<!DOCTYPE svg PUBLIC "-//W3C//DTD SVG 1.1//EN" "http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd">

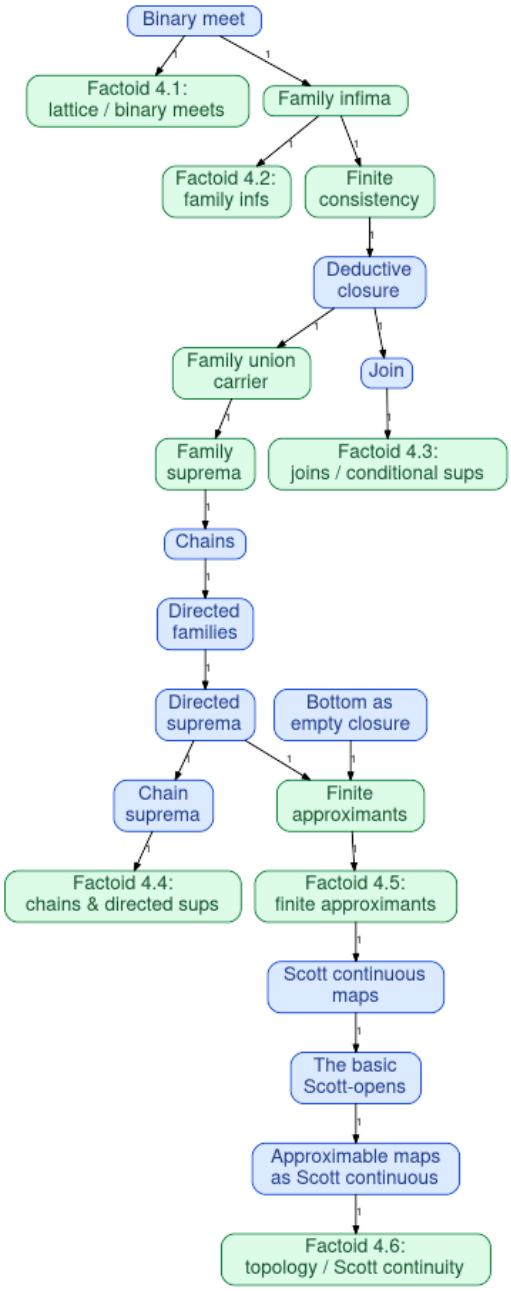

Figure 57: Diagram 22

5.4.1 Introduction

I will attempt to keep this section as informal as possible—especially as Sections 2 and 3 were quite formal (i.e. mathematical) enough. The main purpose of the discussion of this section is to relate the new presentation of the Theory of Domains to previously published ones. (Some alternatives are discussed at the end of the paper.)

5.4.2 Binary meet

Definition (`InfoSys.inf`). The binary meet of two elements is the element whose carrier is the intersection of their carriers. Intersection of consistent deductively closed sets is again consistent and deductively closed, so the result is an element.

Theorem (`InfoSys.inf.le_left`). The binary meet of x and y approximates x.

Proof. Intersection is a subset of the left factor. ?

Theorem (`InfoSys.inf.le_right`). The binary meet of x and y approximates y.

Proof. Intersection is a subset of the right factor. ?

Theorem (`InfoSys.inf.le_inf`). If x approximates both y and z, then x approximates their binary meet.

Proof. Membership in x yields membership in both carriers, hence in their intersection. ?

Theorem (`InfoSys.inf.le_iff_eq`). An element x approximates y if and only if the binary meet of x and y equals x.

Proof. One direction uses the left projection of the meet together with the universal property of intersection under the order hypothesis; the converse recovers the second factor from the carrier equality. ?

Theorem (`InfoSys.inf.le_iff`). An element approximates a binary meet if and only if it approximates both arguments.

Proof. Combine the two projections of the meet with the universal property of the meet. ?

Theorem (`InfoSys.inf.comm`). Binary meet is commutative.

Proof. Each side approximates both arguments of the other, so the two meets coincide by antisymmetry. ?

Theorem (`InfoSys.inf.assoc`). Binary meet is associative.

Proof. Each association approximates the three factors of the other via the projections and the universal property of the meet. ?

Theorem (`InfoSys.inf.idem`). The binary meet of an element with itself is that element.

Proof. Reflexivity of the order together with the absorption characterization of the meet. ?

Theorem (`InfoSys.inf.mono`). Binary meet is monotone in each argument.

Proof. Transport the projections of the smaller meet along the given inequalities, then apply the universal property. ?

Theorem (`InfoSys.inf.botElement_inf`). The binary meet of the bottom element with any element is bottom.

Proof. Bottom approximates every element, so absorption yields the claim. ?

Theorem (`InfoSys.inf.inf_botElement`). The binary meet of any element with bottom is bottom.

Proof. Commute the meet and apply the previous theorem. ?

5.4.3 Factoid 4.1: lattice / binary meets

Lattice-theoretic considerations. Let $\mathbf{A}$ be an information system. Because the elements of $|\mathbf{A}|$ are introduced as sets, these elements can be given structure from what we know already about ordinary sets. For instance, the set-theoretic inclusion relation between sets can certainly be applied to elements. The question is: What does $x \subseteq y$ mean intuitively? In fact, we have already mentioned this relationship before. It means that every proposition (among the ones given by the information system) true of x is also true of y (though not necessarily conversely). In other words, x is perhaps only partially determined, while y is more fully determined in a way that includes everything true of x. Clearly, then, if we grant the interest of partial elements, then this relation is a natural and basic one. We often read "$x \subseteq y$" as "x approximates y".

Now here is one of the main points of the new exposition: Because $x \subseteq y$ is *defined* in terms of a familiar mathematical notion, then as a relation between elements it inherits all the well-known properties of the set-theoretical relation. It should not be necessary to write them out, for everyone who can read this far knows that $\subseteq$ is in particular reflexive and transitive. We say that the domain $|\mathbf{A}|$ is a *partially ordered set under inclusion*. We note that this (trivial) result is *proved* from the definition rather than assumed as an axiom.

Let us try out another notion. Elements are consistent, deductively closed sets of data objects. Right? Every subset of a consistent set is consistent, but not every subset is closed under entailment, in general. Right? But suppose that x and y are two elements. It can easily be seen that their intersection $x \cap y$ is again consistent and deductively closed (by a 2 nanosecond proof). Therefore, the set of elements of a domain is closed under intersection. This means that, as a partially ordered set, $|\mathbf{A}|$ is an *inf semilattice*.

Well, the exact terminology is quite unimportant, but the properties of $\cap$ when combined with the properties of $\subseteq$ are pleasantly "algebraic" (and run to several lines when written out). We all know them: $\cap$ is idempotent, commutative, and associative. The element $\bot$, being the

The element $\bot$, being the smallest element of the domain, is a zero element for $\cap$. The operation $\cap$ is monotonic with respect to $\subseteq$, and we have the connection:

$$x \subseteq y \text{ iff } x \cap y = x.$$

What has just been alluded to in words is the standard mathematical axiomatization of the properties of an infimum (or meet) operation in a partially ordered set. (Remember, however, to have an operation well defined within a set it is necessary also to have closure under that operation.)

Theorem (`InfoSys.factoid_41`). For elements x and y of an information system, x approximates y if and only if the binary meet of x and y equals x.

Proof. This is the order–meet absorption law for binary infima of elements. ?

5.4.4 Family infima

Definition (`InfoSys.familyInfCarrier`). The carrier of a nonempty family's meet is the set of data belonging to every element of the family.

Definition (`InfoSys.familyInf`). The meet of a nonempty family of elements is the element with that intersection carrier. Consistency and deductive closure follow from those of any member of the family, since every finite set of data in the intersection lies in each member.

Theorem (`InfoSys.familyInf.le`). The family meet approximates every member of the family.

Proof. A datum in the intersection carrier belongs to that member. ?

Theorem (`InfoSys.familyInf.le_of`). An element that approximates every member of a nonempty family approximates the family meet.

Proof. Membership in the lower bound yields membership in every member's carrier, hence in the intersection. ?

Theorem (`InfoSys.familyInf.le_iff`). An element approximates a family meet if and only if it approximates every member of the family.

Proof. Combine the projection of the meet onto members with the universal property of the meet. ?

Theorem (`InfoSys.familyInf.pair`). The family meet of a two-element set equals the binary meet of those elements.

Proof. Each side approximates both elements (or both arguments of the binary meet), so the two meets coincide by antisymmetry. ?

5.4.5 Factoid 4.2: family infs

What about infs of subsets? No problem. For any *non-empty* subfamily of $|\mathbf{A}|$, it is just as easy to prove that the set-theoretical intersection of all the elements in the subfamily is again an element of the domain. This makes $|\mathbf{A}|$ a (conditionally) complete inf semilattice. Even if you do not have any idea what I am talking about, it does not matter because the properties of the domain are built in by the very definition; you do not have to worry *at the start* about their formulation, for you can prove them when you need them (if ever).

Theorem (`InfoSys.factoid_42`). The meet of a two-element family of elements equals the binary meet of those two elements.

Proof. This is the binary special case of the family-meet construction. ?

`factoid_42.lean`

```

theorem factoid_42 :
    ∀ {α : Type*} [DecidableEq α] (sys : InfoSys α) (x y : sys.Element),
      sys.familyInf ({x, y} : Set sys.Element) ⟨x, Set.mem_insert x {y}⟩ = sys.inf x y
    :=
  @familyInf.pair

end DomainTheory.InformationSystems.InfoSys
```

5.4.6 Finite consistency

Definition (`InfoSys.IsFinitelyConsistent`). A set of data is finitely consistent when every finite subset is consistent in the information system.

Theorem (`InfoSys.IsFinitelyConsistent.exists_entSet_of_subset_deductive`). If U is finitely consistent and every member of a finite set Y is entailed by some finite subset of U, then some finite subset of U entails every member of Y.

Proof. Induct on Y. The empty case is immediate. For an inserted datum, take finite antecedents for the new datum and for the remainder, form their finite union (still inside U, hence consistent by finite consistency), and obtain multiary entailment of the whole by transitivity of entailment from each piece. ?

5.4.7 Deductive closure

Definition (`InfoSys.deductiveClosure`). The deductive closure of a finitely consistent set U is the element whose carrier consists of every datum entailed by some finite subset of U. Consistency of finite subsets of that carrier follows by gathering their antecedents into one finite subset of U and applying the consistency consequence of multiary entailment; deductive closure of the carrier uses the same gathering together with transitivity of entailment.

Theorem (`InfoSys.deductiveClosure.subset`). A finitely consistent set is contained in the carrier of its deductive closure.

Proof. Each datum of U is entailed by its singleton, which is consistent by finite consistency. ?

5.4.11 Factoid 4.3: joins / conditional sups

What about suprema (or sups or joins)? Here there is a slight problem, because in the way we set things up they *do not* always have to exist. Consider what happens with just two elements x and y. The set-theoretical union of the two elements as subsets of $D_{\mathbf{A}}$ need be neither consistent nor deductively closed; and even if $x \cup y$ is consistent, it need not be closed under entailment. So if we want sups *within* $|\mathbf{A}|$, we cannot get by as cheaply as we can with a domain of arbitrary sets for which the simple union is the answer.

Let us write the sup (supposing it exists in $|\mathbf{A}|$) as $x \sqcup y$. What do we have when we actually have it? By the lore of partially ordered sets, $x \sqcup y$ must be the *least element* in $|\mathbf{A}|$ which includes (in the sense of $\subseteq$) both x and y. Now we have just spoken about infs of families of elements: they exist if the family is non-empty. This indicates that $x \sqcup y$ exists exactly when there is at least one element z in $|\mathbf{A}|$ such that

$x \subseteq z$ and $y \subseteq z$. This turns out to be a way to say—entirely inside $|\mathbf{A}|$—that $x \cup y$ is consistent. In other words (and more generally) a sup of a subfamily exists if, and only if, the union of the family is consistent. (And in that case the sup is just the deductive closure of the union—that is, it is generally larger than the simple set-theoretical union.) This has an axiomatic version, but it is slightly complicated by the fact that sups do not always exist. In case $\top_{\mathbf{A}}$ exists, then we always have all the sups, and $|\mathbf{A}|$ is a *complete lattice*. (This is discussed in full axiomatic splendor in [**?**].) But, let it hasten to be added, not every complete lattice is isomorphic to a domain. The lattices that correspond to domains are the so-called *algebraic lattices*. (See the discussion loc. cit. for the additional axiomatics required.) When the top is missing, the partially ordered structures corresponding to domains are called *conditionally complete, algebraic cpo's*.

Theorem (`InfoSys.factoid_43`). Two elements have a common upper bound if and only if the union of their carriers is finitely consistent.

Proof. This is the binary join existence criterion. ?

`factoid_43.lean`

5.4.16 Factoid 4.4: chains & directed sups

There is, however, an important case in $|\mathbf{A}|$ where the union is consistent and is, in fact, the sup in the domain. Suppose we have a sequence of elements such that

$$x_0 \subseteq x_1 \subseteq x_2 \subseteq \cdots \subseteq x_n \subseteq x_{n+1} \subseteq \cdots$$

As n increases, we can say that the elements x_n are getting "better and better"; thus, they must be approaching something even more desirable *in the limit*. Let

$$y = \bigcup_{n=0}^{\infty} x_n,$$

then there is no question that y is a subset of $D_{\mathbf{A}}$. But is it an element? Consistency, recall, means that every *finite* subset is in $\mathrm{Con}_{\mathbf{A}}$. The trick is that a finite subset of y must be a subset of one of the x_n, because the sequence of elements x_n is increasing. But all the terms of our given sequence are elements, and so, consistent; therefore, every finite subset of y is consistent.

The same argument also shows that the set y of data objects is closed under entailment, because $\vdash_{\mathbf{A}}$ is defined as a relation between finite (consistent) sets and data objects. It follows that since each x_n is a set closed under $\vdash_{\mathbf{A}}$, then so is y. In other words, y is indeed an element. Otherwise said, the domain $|\mathbf{A}|$ is closed under the formation of unions of increasing chains of elements, and the union is, of course, the sup in the sense of the partial ordering. Again we have proved closure rather than assuming it, and the necessary properties of the sup follow from its definition as a union.

This last argument can be generalized—as is well known to mathematicians—to the case of *directed* families of elements. The word "directed," or better "upward-directed," means that every finite number of elements in the family is included in some further element of the family; chains always have this property. A good example of the use of directed sets of elements figures in the discussion of the *finite elements* of the domain.

Theorem (`InfoSys.factoid_44`). The carrier of the directed supremum of a nonempty directed family equals the family-union carrier.

Proof. This is the carrier-equality property of directed suprema. ?

5.4.19 Factoid 4.5: finite approximants

As we have remarked several times, any consistent set of data objects *generates* an element by closing it up under the entailment relation; thus, in particular, any set $u \in \mathrm{Con}$ generates an element. Let us write

$$\overline{u} = \{X \in D_{\mathbf{A}} \mid u \vdash_{\mathbf{A}} X\}$$

for the *closure* of u under entailment. (This notation could be used for any consistent subset of $D_{\mathbf{A}}$, but the case of finitely generated elements is especially important.) Such a $\overline{u}$ is always an element of $|\mathbf{A}|$; the totality of such elements form, by definition, the *finite elements* of the domain. The notation $\overline{u}$ should of course be decorated with a subscript $\mathbf{A}$, but, as there is no good place to write it in, we leave it out.

We have for all elements x of the domain the basic formula:

$$x = \bigcup \{\overline{u} \mid u \in \mathrm{Con}_{\mathbf{A}} \text{ and } u \subseteq x\}.$$

This can be read intuitively as saying that every element of the domain is the *limit* of its *finite approximations*. And, having used the word "limit" so often, we ought now to say something about how to make the meaning of this word correct mathematically. Note that in the limit representation for x, the union is a directed one. (Why?)

Theorem (`InfoSys.factoid_45`). Every element equals the directed supremum of its finite approximants.

Proof. This is the directed-supremum representation of an element by its finite approximants. ?

5.4.22 Approximable maps as Scott continuous

Theorem (`InfoSys.ApproximableMap.toElement_directedSup`). The element map of an approximable mapping preserves directed suprema.

Proof. Finite relational witnesses for data in the image of the directed supremum sit in some member of the family by directedness; the reverse inequality is monotonicity of the element map. ?

Definition (`InfoSys.ApproximableMap.ofScottContinuous`). From a Scott-continuous map one obtains an approximable mapping by relating consistent finite sets u and v when v lies in the image of the closure of u. Consistency and monotonicity of the relation follow from those of the Scott-continuous map and of closure.

Definition (`InfoSys.ApproximableMap.toScottContinuous`). From an approximable mapping one obtains a Scott-continuous map by taking its element map, using that the element map is monotone and preserves directed suprema.

Theorem (`InfoSys.ApproximableMap.toElement_ofScottContinuous`). Passing from a Scott-continuous map to an approximable mapping and back recovers the original map on elements.

Proof. One inequality is monotonicity applied to closures of relational antecedents; the other uses the finite-approximant representation of the argument together with preservation of directed suprema. ?

5.4.23 Factoid 4.6: topology / Scott continuity

Topological considerations. Geometrically speaking, a topological space is a collection of "points" which group themselves in various "neighborhoods" providing thereby a sense of "nearness." More specifically, a neighborhood of a point in a *metric space* consists of all those points within a certain positive "distance" from the given point; that is, nearness is limited, but it is not pushed to *zero*. The major reason for leaving some "breathing space" around the point comes out in defining continuity of functions.

A function f from one topological space to another is said to be *continuous* provided that, for every point x of the first space, and for every neighborhood in the second space around $f(x)$, it is

possible to find—in the first space—a neighborhood around x with the following property. If the function is restricted to this neighborhood, then its values lie entirely in the given neighborhood around $f(x)$. In the metric case we can say that if we do not want the function to wander any great distance from $f(x)$, then there is a restricted distance around x giving a neighborhood over which the function values stay as close to $f(x)$ as specified. This keeps the function from jumping around wildly, since small variations in x lead to only small variations in $f(x)$.

The intuition about continuity is no doubt very clear in the more geometric examples, and geometric intuition can carry us quite far. But the spaces obtained from domain theory are not really geometric spaces, so we need to make some shifts in our metaphors. The geometric notion of a point usually implies that two points are perfectly distinguishable: if x and y are different, then they have disjoint neighborhoods. This is certainly true in the metric case, where, if two points are different, then they are at a positive distance apart. Early on in the study of topological spaces, however, it was found that not all spaces were metric, and weaker separation properties of pairs of distinct points were uncovered. One of the very weak versions of such a condition is called the "T_0-axiom." The best way to put it is that if two points have the same neighborhoods, then they are the same. The contrapositive statement sounds odd: if two points are distinct, then there is a neighborhood that contains one but not the other. The oddity of this statement lies in the feeling that you cannot make up your mind over which is the better point.

In our domains there is already a notion of "betterness" which proves to be very closely related to the implicit neighborhood structure. The reason why our domains, as spaces of points, are not "geometric" in the familiar sense is that they contain partial elements. A geometric point, on the other hand, is "perfect" or totally determined; it cannot be made better than it already is. The metric in common spaces is measuring something other than betterness, for there are competing notions of approximation afoot here. Thus, we must keep our special goals in defining domains clearly in mind to avoid confusion.

Consider an information system $\mathbf{A}$. For each $u \in \mathrm{Con}_{\mathbf{A}}$, we define a corresponding neighborhood of $|\mathbf{A}|$ by the equation:

$$[u]_{\mathbf{A}} = \{x \in |\mathbf{A}| \mid u \subseteq x\}.$$

The neighborhoods of an element x are all those sets $[u]_{\mathbf{A}}$, where $u \subseteq x$. Note that this is the same as saying $\overline{u} \subseteq x$ or $\overline{u}$ approximates x. Indeed, the neighborhoods are in a one-one correspondence with the finite elements of $|\mathbf{A}|$. A neighborhood collects together all those elements sharing the same finite amount of information.

If both $u \subseteq x$ and $v \subseteq x$, then it is easy to see that the intersection of the two neighborhoods is again a neighborhood of x by virtue of the formula:

$$[u]_{\mathbf{A}} \cap [v]_{\mathbf{A}} = [u \cup v]_{\mathbf{A}}.$$

In case u and v are inconsistent with each other, then the intersection will be the empty set $\emptyset$. Because every element of our domain $|\mathbf{A}|$ is the union of the finite elements it contains, it is trivial to prove that two elements with exactly the same neighborhoods are the same. For these reasons, then, it follows that $|\mathbf{A}|$ is a T_0-topological space. The immediate reaction to this intelligence is: So what?

The answer to this scepticism will appear in the best light when we discuss in the next section the notion of function or mapping appropriate to our domains. The argument will be based on the

extremely elementary form of the definition that characterizes the general continuous function together with the fact that the geometric intuition is suggestive of theorems to prove. In Section 6 we will find that the space of all continuous functions between two given domains is also a domain, a most useful result that is interesting topologically. But further interest for Domain Theory comes from the circumstance that there is a connection between geometry and domains. We cannot go into the full details here, but I can make some brief remarks.

Before continuing that discussion, though, it should be remarked that once the topology of the domain has been uncovered, then the unions of chains of elements (or directed sets of elements) are topological limits according to accepted general definitions. Thus, what we felt intuitively was a limiting process (the getting better and better up to the union) is in fact a limit formation in a precise mathematical sense. This helps convince us that we are on the right track.

Total elements as a space. In any domain it can be proved that any element x can be extended to a *total element* t, which is characterized by the property that it is a *maximal* element of the partial ordering. (Perhaps there are many such t, but there is always at least one with $x \subseteq t$.) Recall that the set of all total elements of $|\mathbf{A}|$ is denoted by $\mathrm{Tot}_{\mathbf{A}}$. Because the set $\mathrm{Tot}_{\mathbf{A}} \subseteq |\mathbf{A}|$, it is a topological space itself. Suppose s and t are two distinct total elements, then they must be inconsistent with each other—but we shall prove more. If every finite consistent $u \subseteq s$ also satisfied $u \subseteq t$, then $s \subseteq t$ would follow. But this is impossible, because s is maximal. Let, then, $u \in \mathrm{Con}_{\mathbf{A}}$ with $u \subseteq s$ be chosen so that $u \subseteq t$ fails. Now u must be inconsistent with t, since otherwise there would be an element containing them both. It follows that u must be inconsistent with some $v \in \mathrm{Con}_{\mathbf{A}}$ with $v \subseteq t$. In this way we show that the neighborhoods $[u]_{\mathbf{A}}$ and $[v]_{\mathbf{A}}$ are disjoint.

This argument proves that $\mathrm{Tot}_{\mathbf{A}}$ is a *Hausdorff space* (or T_2-space). We cannot go further into the details here, but it is also a totally disconnected, compact Hausdorff space. (These spaces—well known from studies of Logic and the Theory of Boolean Algebras—are also zero-dimensional.) Assuming the countability of $\mathrm{Con}_{\mathbf{A}}$, which is not such a bold assumption, all such spaces can be conveniently embedded into the real line so as to preserve the topological structure. Perhaps this does not seem so surprising, but it shows that the topological nature of $\mathrm{Tot}_{\mathbf{A}}$, the uppermost level of the T_0 space $|\mathbf{A}|$, is indeed quite geometric. And it can also be shown that any arbitrary continuous function on $\mathrm{Tot}_{\mathbf{A}}$ into *any* topological space can be extended to a continuous function on $|\mathbf{A}|$, so the whole domain proves to be quite a "roomy" space with many good connections to more usual topological spaces.

A note on neighborhood structures. Topological spaces can be defined in several ways, and in general

they do not carry a preferred neighborhood structure. (For example, there is no topological significance to the usual rational intervals we use to define neighborhoods for the real line: any similarly dense set of points would do in place of the rational numbers.) Domains, the way we have defined them, however, do have preferred neighborhoods. The set of finite elements of $|\mathbf{A}|$ can be defined topologically, and as we have seen they determine a convenient set of neighborhoods. (The reason for all this is the so-called zero-dimensional character of the domains. There is a higher-dimensional theory, but this leads to continuous lattices and can only be explained using the kind of presentation in [**?**]. It is too long-winded a story for the present paper. The higher-dimensional domains do not have a preferred set of neighborhoods, however.)

Having realized this, it is a short step to giving an algebraic axiomatization of the neighborhood structure. [**?**] contains a presentation in terms of the equivalent notion of finite element. [2] turns the story around and defines a set-theoretical representation of a neighborhood as just a family of sets containing a largest "neighborhood" and closed under forming the intersection of any two sets in the family that contain a third. The set-theoretical form of this definition is very simple, and [2] spells out the details of how the theory of domains can be based on this starting point. Subsequent investigation, however, has convinced the author that the present approach through information systems is even simpler and better for a number of the essential constructions. The theory introduced by [**?**] of f-spaces is another axiomatization somewhat intermediate between the topological and the lattice-theoretic. Domains in the present sense then become complete f-spaces. There are many interesting aspects to this method, but the author feels that information systems are about as elementary and familiar as we can get, and they are therefore more suggestive of new constructions.

Theorem (`InfoSys.ApproximableMap.factoid_46`). Passing from a Scott-continuous map to an approximable mapping and back recovers the original map on elements.

Proof. This is the recovery property of the Scott-continuous–to–approximable correspondence. ?

5.5 Approximable mappings between domains

<!DOCTYPE svg PUBLIC "-//W3C//DTD SVG 1.1//EN" "http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd">

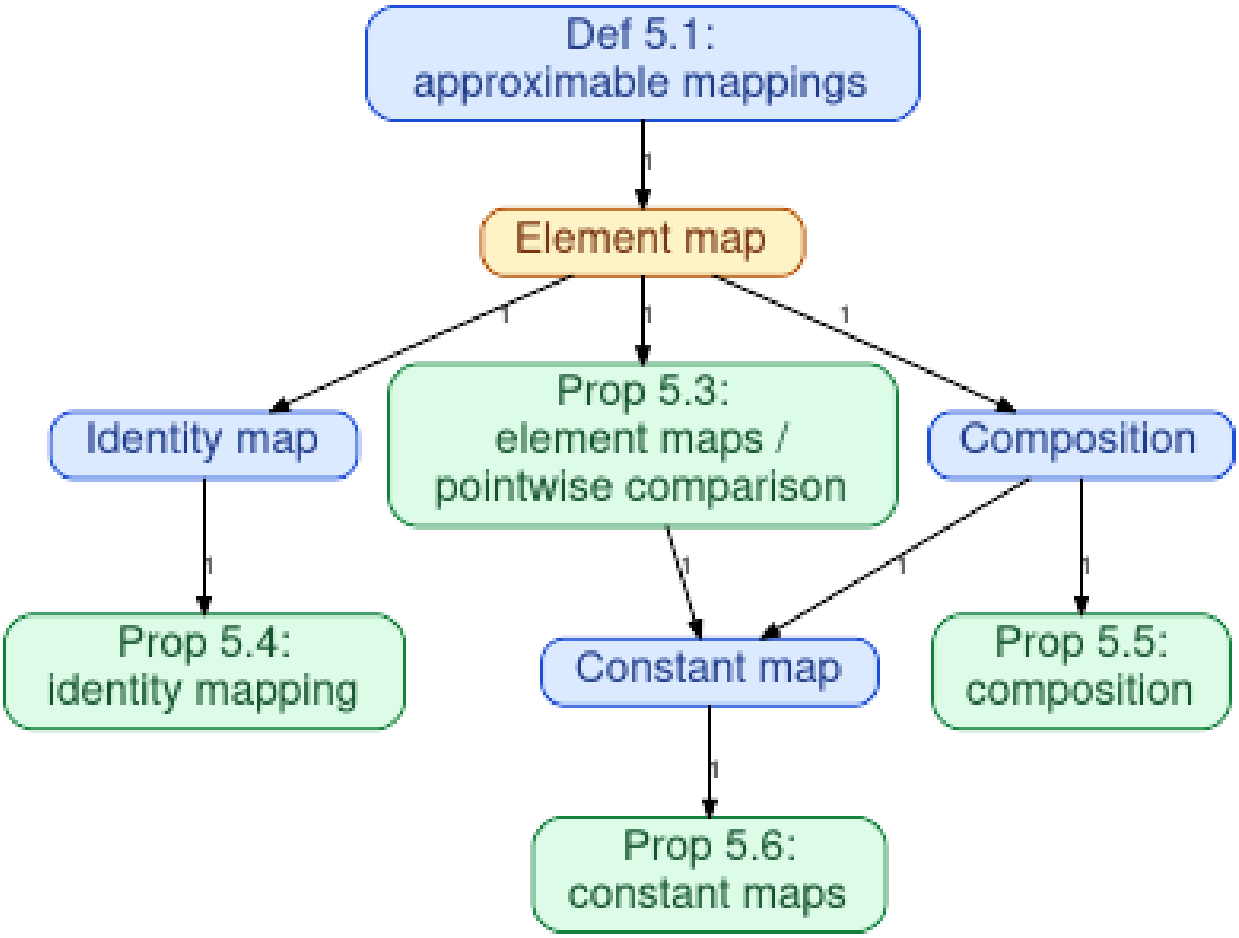

Figure 58: Diagram 23

5.5.1 Introduction

Once a general notion of set or domain has been defined mathematically, the next major issue is: How are the different domains to be related one to another? The answer to this important question can many times be given by defining an appropriate concept of mapping between domains. The answer need not be unique; the same collection of domains may support more than one idea of function depending on the special aspects of the domains that need to be brought out. In the case of the kinds of domains being studied here, there are two principal answers, one of which is to be explained in this section.

In order to understand an appropriate notion of a mapping or a function between domains constructed from information systems, we have to refer back to the way in which elements are introduced. As we have seen in Section 3, an element is a consistent, closed set of data objects. To generate an element, one has to generate more and more of the finite consistent subsets of the element. Note that the separate data objects have to be grouped into these finite consistent sets, because the entailment relation may require a finite set of arbitrary size on the left in making the necessary entailments for closure. It is this kind of passage from a finite set to its closure that is to be generalized in defining mappings.

Consider two domains. To map from one to another, some information about a possible element of the first is presented as input to the function f. Then as output the function f starts generating an element. If

the input were u, a consistent set of the first domain, then part of the output in the second domain might be a consistent set v. We could say that there is an input/output relationship set up by f, and indicate by $u\ f\ v$ that this relation holds going from u in the first domain to v in the second. Of course to get the full effect of f, it is necessary to take all the v's related to a given u, because even a small finite amount of input may cause an infinite amount of output. But every element of a domain is just the sum total of its finite subsets (finite approximations), so it is sufficient to make the mapping relationship go between finite sets. Here is the formal definition with the exact conditions that the relation f must satisfy.

5.5.2 Definition 5.1: approximable mappings

DEFINITION 5.1. Let $\mathbf{A}$ and $\mathbf{B}$ be two given information systems. An *approximable mapping* $f : \mathbf{A} \to \mathbf{B}$ is a binary relation between the two sets $\mathrm{Con}_{\mathbf{A}}$ and $\mathrm{Con}_{\mathbf{B}}$ such that:

(i) $\emptyset\ f\ \emptyset$;

(ii) $u\ f\ v$ and $u\ f\ v'$ always imply $u\ f\ (v \cup v')$; and

(iii) $u' \vdash_{\mathbf{A}} u$, $u\ f\ v$, and $v \vdash_{\mathbf{B}} v'$ always imply $u'\ f\ v'$.

We say that $\mathbf{A}$ is the *source* of f and $\mathbf{B}$ is the *target*. ■

Intuitively the relationship $u\ f\ v$ is an input/output passage which can be read informally as: "if you are willing to give at least u amount of information about the argument, then the mapping f is willing to give at least v amount of information about the value (and possibly even more—if you are patient)." Condition (i) means that no (non-trivial) information about the input merits no information about the output. Condition (ii) implies that all the contributions to the output from a fixed input are consistent, and in fact the union of two of the output sets is again an output set. Output corresponding to a fixed input is cumulative. Condition (iii) assures us that the mapping relation f works in harmony with the two entailment relations: if a certain relationship holds, and if the left-hand side is strengthened while the right-hand side is weakened, then the mapping relation must continue to hold. What we must discuss next is what this means for elements.

Before defining the notion of function value, however, it is useful to remark that in the definition of approximable mapping the form of the statement could be simplified by reducing sets on the right to their elements. Specifically, we note the equivalence:

$$u\ f\ v \text{ iff } u\ f\ \{Y\} \text{ for all } Y \in v.$$

In other words an approximable mapping is completely determined by the relation set up between consistent sets on the left and single data objects on the right.

Definition (`InfoSys.ApproximableMap`). An approximable mapping from an information system $\mathbf{A}$ to an information system $\mathbf{B}$ is a relation between finite sets of data of $\mathbf{A}$ and of $\mathbf{B}$ that relates only consistent sets on each side, relates the empty set to the empty set, is closed under funion on the right for a fixed left argument, and is monotone with respect to entailment—strengthening the left argument and weakening the right preserves relatedness, provided both sides remain consistent.

Definition (`InfoSys.ApproximableMap.Le`). One approximable mapping lies below another when every related pair of the first is related by the second.

Theorem (`ApproximableMap.ext`). Two approximable mappings are equal precisely when they relate the same consistent sets.

Proof. The relation field determines the structure. ?

5.5.3 Element map

Theorem (`ApproximableMap.exists_rel_of_subset_image`). If every token of a finite set Y arises from some approximable input under an element x, then some single consistent input under x relates to the whole of Y.

Proof. Empty Y uses the empty relation after weakening; the inductive step joins the witnesses for the new token and the remainder via right-union and monotonicity. ?

Definition (`ApproximableMap.toElement`). The element map of an approximable mapping f sends an element x of the source to the element of the target whose tokens are those Y for which some finite input under x relates to $\{Y\}$.

Theorem (`ApproximableMap.mem_toElement`). Membership in the carrier of the element map is exactly the witnessing relation of the definition.

Proof. Unfolding. ?

Theorem (`ApproximableMap.toElement_mono`). The element map is monotone.

Proof. A witnessing input under a smaller element remains under a larger one. ?

Theorem (`ApproximableMap.rel_iff_closure_le`). Consistent sets u and v are related by an approximable mapping if and only if the closure of v approximates the image of the closure of u.

Proof. Relatedness yields singleton witnesses under the left closure; conversely a relational witness under the left closure is weakened back to u and v by monotonicity. ?

Theorem (`ApproximableMap.le_iff_toElement_le`). One approximable mapping lies below another if and only if its element map approximates the other's at every source element.

Proof. Pointwise comparison of images preserves relational witnesses; conversely the closure characterization transfers a related pair through the pointwise inequality. ?

Theorem (`ApproximableMap.ext_iff_toElement`). Two approximable mappings are equal if and only if they agree as element maps on every source element.

Proof. Equality of maps yields pointwise equality of images; conversely mutual pointwise order via the order characterization forces equal relations. ?

5.5.4 Definition 5.2: image / function value

DEFINITION 5.2. If $f : \mathbf{A} \to \mathbf{B}$ is an approximable mapping between information systems, and if $x \in |\mathbf{A}|$ is an element of the first, then we define the *image* (or *function value*) of x under f by the formula:

$$f(x) = \{Y \in D_{\mathbf{B}} \mid u \; f \; \{Y\} \text{ for some } u \subseteq x\}.$$

Alternatively, we could use the equivalent formula:

$$f(x) = \bigcup\{v \in \mathrm{Con}_{\mathbf{B}} \mid u \; f \; v \text{ for some } u \subseteq x\}. \blacksquare$$

Note that, under Definition 5.2, it has to be *proved* that the image of an element in $|\mathbf{A}|$ lies in $|\mathbf{B}|$ in order to justify the use of the ordinary function-value notation. But both the consistency and the closure under entailment of $f(x)$ are direct consequences of the properties in the definition of approximable mapping.

Definition (`ApproximableMap.toElement`). The image of an element under an approximable mapping is the element map already recorded with Definition 5.1's companions: its carrier is exactly the first formula above, and constructing a target element settles the consistency and deductive-closure obligations Scott notes after the definition.

5.5.5 Proposition 5.3: element maps / pointwise comparison

PROPOSITION 5.3. *Let $f, g : \mathbf{A} \to \mathbf{B}$ be two approximable mappings between two information systems. Then*

(i) f always maps elements to elements under Definition 5.2;
(ii) $f = g$ iff $f(x) = g(x)$ for all $x \in |\mathbf{A}|$; and
(iii) $f \subseteq g$ iff $f(x) \subseteq g(x)$ for all $x \in |\mathbf{A}|$.
Moreover, the approximable mappings are monotone in the sense that

(iv) $x \subseteq y$ in $|\mathbf{A}|$ always implies $f(x) \subseteq f(y)$ in $|\mathbf{B}|$.

All these results follow from the observation that

(v) $u \; f \; v$ iff $\bar{v} \subseteq f(\bar{u})$,

for all $u \in \mathrm{Con}_{\mathbf{A}}$ and all $v \in \mathrm{Con}_{\mathbf{B}}$. ■

The proof is straightforward, and it completely justifies the use of the function-value notation. Consequently, the question arises as to whether the characterization of approximable mappings could not have been given in terms of elements in the first place. The answer is yes. Indeed, approximable mappings correspond exactly to functions on elements preserving unions of chains (this, in the case of countable information systems; directed unions must be used in general). This characterization has also been called "continuity," because it is equivalent to saying that the mappings between elements are continuous mappings in the topological sense, when $|\mathbf{A}|$ and $|\mathbf{B}|$ are regarded as topological spaces, as explained in the last section. The reason for the word "approximable" is explained in Section 7.

Having justified the idea of an approximable mapping as a transformation on elements, the next step is to combine mappings. It is hardly surprising to learn that compositions of approximable mappings are approximable, which in mathematical terms means that the domains together with the approximable mappings form a *category*. The interesting part starts when we want to combine *domains*. But, to fix ideas, it is useful to spell out how compositions take place on the level of the data objects and consistent sets. For instance, it was noted that in any information system $\vdash$ is transitive on Con, and in Definition 5.1 a transitivity condition comes in. There is a perfectly good reason for the parallelism, for, as we see next, the first idea (entailment) is a special case of the second (approximable mapping).

Theorem (`ApproximableMap.proposition_5_3`). Two approximable mappings are equal precisely when they agree as element maps; one lies below another precisely when its element map approximates the other's pointwise; and relatedness of consistent sets is equivalent to the closure of the right argument approximating the image of the closure of the left.

Proof. Assemble pointwise equality, pointwise order, and the relation-via-closures characterization. (Mapping elements to elements, and monotonicity of the element map, are already settled with the image.) ?

5.5.6 Identity map

Definition (`InfoSys.idMap`). The identity approximable mapping on an information system relates consistent sets u and v precisely when u entails v.

Theorem (`InfoSys.idMap.toElement`). The element map of the identity approximable mapping is the identity on elements.

Proof. Relatedness yields entailment of singletons, so tokens of the image lie in the source element by closure; conversely each token is recovered from its singleton via reflexivity of entailment. ?

5.5.7 Proposition 5.4: identity mapping

PROPOSITION 5.4. *Let* $\mathbf{A}$ *be an information system. Then the following formula defines an approximable mapping* $I_{\mathbf{A}} : \mathbf{A} \to \mathbf{A}$*:*

(i) $u \; I_{\mathbf{A}} \; v$ iff $u \vdash_{\mathbf{A}} v$,

for all $u, v \in \mathrm{Con}_{\mathbf{A}}$*. And we have:*

(ii) $I_{\mathbf{A}}(x) = x$,

for all $x \in |\mathbf{A}|$. ■

In other words, the given entailment relation itself defines the identity function on the domain in question; and of course, the identity function is an approximable mapping.

Theorem (`InfoSys.proposition_5_4`). The identity approximable mapping acts as the identity on elements.

Proof. The identity map's element-map lemma. ?

5.5.9 Proposition 5.5: composition

PROPOSITION 5.5. *Let $f : \mathbf{A} \to \mathbf{B}$ and $g : \mathbf{B} \to \mathbf{C}$ be two approximable mappings. Then the following formula defines an approximable mapping $g \circ f : \mathbf{A} \to \mathbf{C}$:*

(i) $u\ (g \circ f)\ w$ iff $u\ f\ v$ and $v\ g\ w$ for some $v \in \mathrm{Con}_{\mathbf{B}}$,

for all $u \in \mathrm{Con}_{\mathbf{A}}$ and $w \in \mathrm{Con}_{\mathbf{C}}$. And we have:

(ii) $(g \circ f)(x) = g(f(x)),$

for all $x \in |\mathbf{A}|$. ■

In other words, composition of input/output relations is effected by putting the input into the first, getting some output, and then putting that in as input to the second. The correctness of this

recipe on elements (i.e. formula 5.5(ii)) follows from the basic formula 5.3(v). Because the class of all sets and arbitrary mappings forms a category—in the formal meaning of the word—the above three propositions show that the totality of information systems and approximable mappings also forms a category: a sub-category of the category of sets. We have given a special representation to the category by our use of data objects and consistent sets, and we have thereby put the elements into a secondary position—for a good reason. But the elements are there to use. The axioms for a category could also be verified directly using the basic definitions like 5.4(i) and 5.5(i); the details are bland. The more interesting topic is: what are the closure conditions on our domains; how do we construct new domains given old ones?

Before we go on to the first basic constructs of sums and products of domains, we remark on some other easy examples of approximable mappings: constant maps.

Theorem (`ApproximableMap.proposition_5_5`). The element map of a composition is the composition of the element maps.

Proof. The composition's element-map lemma. ?

5.5.10 Constant map

Definition (`ApproximableMap.constMap`). The constant approximable mapping toward a fixed element b relates a consistent input to a consistent output precisely when the output is contained in b.

Theorem (`ApproximableMap.constMap.toElement`). The element map of a constant approximable mapping is constantly the chosen element.

Proof. Relatedness forces every output token into b; conversely the empty input witnesses every token of b. ?

Theorem (`ApproximableMap.constMap.comp`). Composing a constant map on the left with any map yields the same constant map from the new source.

Proof. Pointwise on elements both sides are constantly b. ?

Theorem (`ApproximableMap.constMap.unique`). An approximable mapping whose element map is constantly b equals the constant map toward b.

Proof. Pointwise equality of element maps. ?

Theorem (`ApproximableMap.constMap.comp_const`). Composing on the right with a constant map toward b yields the constant map toward the image of b.

Proof. Pointwise on elements both sides are constantly the image of b. ?

5.5.11 Proposition 5.6: constant maps

PROPOSITION 5.6. *Given information systems* $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, *and* $\mathbf{D}$, *and given a fixed element* $b \in |\mathbf{B}|$, *then there is a unique approximable mapping* $\mathrm{const}\ b : \mathbf{A} \to \mathbf{B}$ *such that:*

(i) $(\mathrm{const}\ b)(x) = b$,

for all $x \in |\mathbf{A}|$. *Moreover, we have:*

(ii) $f \circ (\mathrm{const}\ b) = \mathrm{const}\ f(b)$,

for all approximable mappings $f : \mathbf{B} \to \mathbf{C}$; *and*

(iii) $(\mathrm{const}\ b) \circ g = \mathrm{const}\ b$,

for all approximable mappings $g : \mathbf{D} \to \mathbf{A}$. ■

The proof is immediate, since we need only interpret the input/output relation $u\ (\mathrm{const}\ b)\ v$ as meaning $v \subseteq b$. We note that our notation is somewhat ambiguous since, for example, in 5.6(iii) we are using $\mathrm{const}\ b$ in two senses: once as a mapping from $\mathbf{A}$, and once as a mapping from $\mathbf{D}$. In fact, we should hang two subscripts on the thing to fix both the source and the target of the mapping. This is too painful, however, and we generally rely on context to make the meaning clear. (Formal rules of type checking can be given, so on a computer-based system all the necessary subscripts could be put back in. Thus, the kind of ambiguity we are dealing with here is not very serious.)

Theorem (`ApproximableMap.proposition_5_6`). Constant approximable mappings act constantly on elements; composing on the right with a constant yields the constant toward the image; composing on the left with a constant leaves that constant unchanged (from the new source).

Proof. Assemble the constant map's element-map, right-composition, and left-composition lemmas. ?

5.6 Products of domains

<!DOCTYPE svg PUBLIC "-//W3C//DTD SVG 1.1//EN" "http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd">

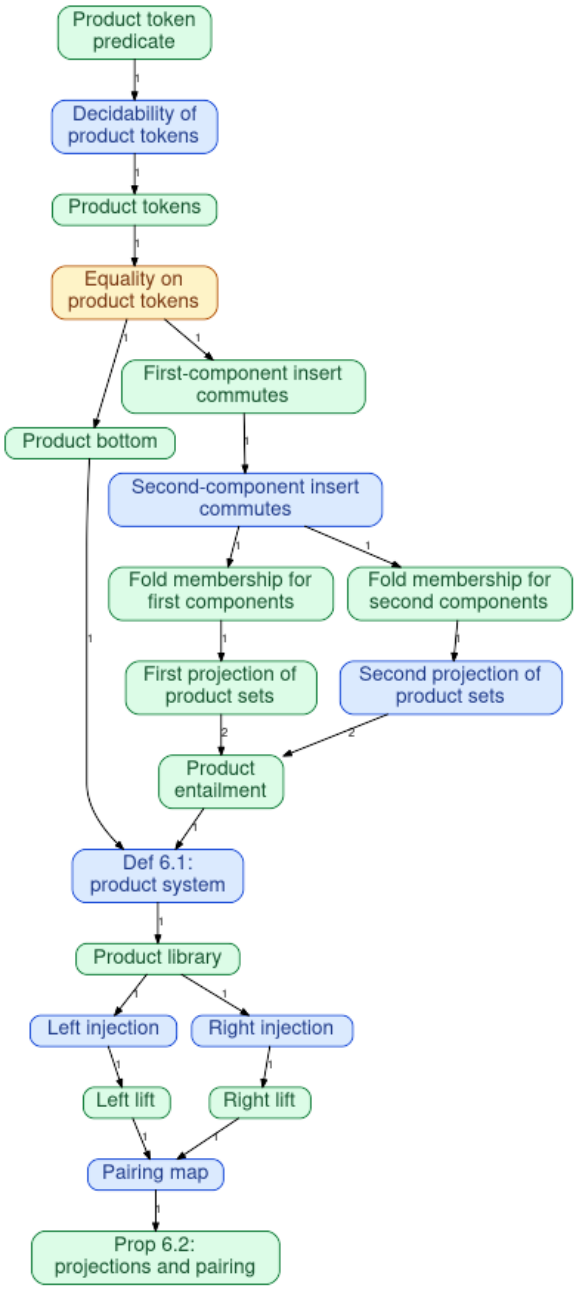

Figure 59: Diagram 24

5.6.1 Introduction

In the category of sets, the product (the cartesian product) of two sets is by definition just the set of ordered pairs of elements. We could use the same definition in the category of domains—provided we worked in terms of the elements of the domains. The disadvantage is that the determination of the product domain from data objects is lost, or at least pushed into the background. We shall therefore give a construction of products directly in terms of the given data objects, and then show how to prove that the product is just the

one expected when we look at the elements.

The idea for the definition is a simple one. Think of two domains $\mathbf{A}$ and $\mathbf{B}$. A data object $X \in D_{\mathbf{A}}$ can be giving information about a possible element $x \in |\mathbf{A}|$, and a data object $Y \in D_{\mathbf{B}}$ can be giving information about a possible element $y \in |\mathbf{B}|$. How do we wish to give information about the pair (x, y)? The first piece of advice is not to say all that is known all at once. For example, if pressed, we can say we know X about the first coordinate of the pair; only later, if really pressed, we can say we also know Y about the second coordinate. The point is that data objects provide only partial information, and it does not matter if it takes several of them to give fairly complete information about the whole element. This attitude motivates, then, the particular form of our official definition.

5.6.2 Product token predicate

Definition (`IsProdToken`). A pair is a product token when at least one component is the corresponding system's bottom.

`IsProdToken.lean`

```
module

public import DomainTheory.InformationSystems.InformationSystems.Constructive
public import DomainTheory.InformationSystems.InformationSystems.EntSet

@[expose] public section

namespace DomainTheory.InformationSystems

open DomainTheory.InformationSystems.Constructive

namespace InfoSys

variable {α β : Type*} [DecidableEq α] [DecidableEq β]

class IsProdToken (A : InfoSys α) (B : InfoSys β) (p : α × β) : Prop where
  out : p.1 = A.bot ∨ p.2 = B.bot

end InfoSys

end DomainTheory.InformationSystems
```

5.6.3 Decidability of product tokens

Definition (`InfoSys.instDecidableIsProdToken`). Membership in the product-token predicate is decidable by inspecting which component is bottom.

`BasicInst5.lean`

```
module

public import DomainTheory.InformationSystems.InformationSystems.Constructive
public import DomainTheory.InformationSystems.InformationSystems.EntSet
public import DomainTheory.InformationSystems.ProductsAndSumsOfDomains.Product.

5.6.11 First projection of product sets

Definition (`fstFinset`). The first projection of a finite set of product tokens collects those left components whose right component is bottom.

Theorem (`mem_fstFinset`). Membership in the first projection matches the existence of a witnessing product token.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`fstFinset.empty`). The first projection of the empty set is empty.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`fstFinset.funion`). First projection preserves finite unions.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`fstFinset.insert_left`). Inserting a left-sided token adjoins its first component.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`fstFinset.insert_not_left`). Inserting a non-left-sided token leaves the first projection unchanged.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`fstFinset.mono`). First projection is monotone.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`fstFinset.singleton_left`). The first projection of a singleton left-sided token is that first component.

Proof. Direct from the definitions and the ambient information-system axioms. ?

5.6.14 Definition 6.1: product system

DEFINITION 6.1. Let $\mathbf{A}$ and $\mathbf{B}$ be two information systems. By $\mathbf{A} \times \mathbf{B}$, the *product system*, we understand the system where:

(i) $D_{\mathbf{A}\times\mathbf{B}} = \{(X, \Delta_{\mathbf{B}}) \mid X \in D_{\mathbf{A}}\} \cup \{(\Delta_{\mathbf{A}}, Y) \mid Y \in D_{\mathbf{B}}\}$;

(ii) $\Delta_{\mathbf{A}\times\mathbf{B}} = (\Delta_{\mathbf{A}}, \Delta_{\mathbf{B}})$;

(iii) $u \in \mathrm{Con}_{\mathbf{A}\times\mathbf{B}}$ iff $\mathrm{fst}\, u \in \mathrm{Con}_{\mathbf{A}}$ and $\mathrm{snd}\, u \in \mathrm{Con}_{\mathbf{B}}$;

(iv') $u \vdash_{\mathbf{A}\times\mathbf{B}} (X', \Delta_{\mathbf{B}})$ iff $\mathrm{fst}\, u \vdash_{\mathbf{A}} X'$; and
(iv' ') $u \vdash_{\mathbf{A}\times\mathbf{B}} (\Delta_{\mathbf{A}}, Y')$ iff $\mathrm{snd}\, u \vdash_{\mathbf{B}} Y'$;
where, in (iii), u is any finite subset of $D_{\mathbf{A}\times\mathbf{B}}$, in (iv') and (iv' '), $u \in \mathrm{Con}_{\mathbf{A}\times\mathbf{B}}$, and we let:

$$\mathrm{fst}\, u = \{X \in D_{\mathbf{A}} \mid (X, \Delta_{\mathbf{B}}) \in u\}, \text{ and}$$

$$\mathrm{snd}\, u = \{Y \in D_{\mathbf{B}} \mid (\Delta_{\mathbf{A}}, Y) \in u\}. \quad \blacksquare$$

Note that in 6.1(i) the two sets in the union are just two copies of $D_{\mathbf{A}}$ and $D_{\mathbf{B}}$, respectively. There is a shared member, however, the object $(\Delta_{\mathbf{A}}, \Delta_{\mathbf{B}})$, which is indeed the least informative data object—whether it is looked at from the point of view of $\mathbf{A}$ or of $\mathbf{B}$. We could have used all the pairs (X, Y), but if we did, the consistent set $\{(X, Y)\}$ would be deductively equivalent to the set $\{(X, \Delta_{\mathbf{B}}), (\Delta_{\mathbf{A}}, Y)\}$ according to the definition of $\vdash_{\mathbf{A}\times\mathbf{B}}$, and so there is not much point in having this redundancy. Strictly speaking, we should not make these remarks until we have actually verified that 6.1 is indeed a proper definition.

Definition (`InfoSys.productSystem`). The product of information systems $\mathbf{A}$ and $\mathbf{B}$ is the information system whose data are the product tokens of Definition 6.1(i), whose least informative object is the shared bottom $(\Delta_{\mathbf{A}}, \Delta_{\mathbf{B}})$, whose consistent sets are those whose first and second projections are consistent in $\mathbf{A}$ and $\mathbf{B}$ respectively, and whose entailment of a token is the corresponding entailment of its first or second component as in 6.1(iv')–(iv' '). The information-system axioms hold by projecting to the two factors and applying their axioms.

Theorem (`ProdEnt.entSet_fst`). Entailment of finite sets in the product projects to entailment of first components in $\mathbf{A}$.

Proof. Each first-component token comes from a product token whose right component is bottom, and the product entailment supplies the corresponding factor entailment. ?

Theorem (`ProdEnt.entSet_snd`). Entailment of finite sets in the product projects to entailment of second components in $\mathbf{B}$.

Proof. Dual to the first-component case. ?

Definition (`productSystem.fstMap`). The first projection approximable mapping from $\mathbf{A} \times \mathbf{B}$ to $\mathbf{A}$ relates a consistent product set u to a consistent set v in $\mathbf{A}$ precisely when u is consistent in the product and the first components of u entail v in $\mathbf{A}$.

Definition (`productSystem.sndMap`). The second projection approximable mapping from $\mathbf{A} \times \mathbf{B}$ to $\mathbf{B}$ relates a consistent product set u to a consistent set w in $\mathbf{B}$ precisely when u is consistent in the product and the second components of u entail w in $\mathbf{B}$.

Theorem (`ApproximableMap.productSystem.element_eq_of_fst_snd`). Two elements of $\mathbf{A} \times \mathbf{B}$ with equal first and second components coincide.

Proof. Each token of one element is recovered in the other using projection and closure, according to whether its right or left component is bottom. ?

5.6.16 Left injection

Definition (`InfoSys.mkLeft`). For $x \in D_{\mathbf{A}}$, the left injection token is $(x, \Delta_{\mathbf{B}})$ with the corresponding half-left product witness.

Definition (`InfoSys.mkLeft.instLeftCommutativeInsert`). Inserting left-injection tokens commutes on the left when building finite sets of product tokens.

mkLeft.lean

5.6.18 Left lift

Definition (`InfoSys.liftLeft`). The left lift of a finite set $v \subseteq D_{\mathbf{A}}$ is the finite set of left-injection tokens $(x, \Delta_{\mathbf{B}})$ for $x \in v$.

Theorem (`InfoSys.liftLeft.mem_foldr`). Membership in a left lift built by folding insertion over a multiset equals membership of some left injection over that multiset.

Proof. Induction on the multiset, using the characterization of insert membership. ?

Theorem (`InfoSys.liftLeft.mem`). A token lies in the left lift of v iff it is a left injection of some $x \in v$.

Proof. Unfold the lift and apply the fold characterization. ?

Theorem (`InfoSys.liftLeft.fstFinset_eq`). The first projection of a left lift is the original set v.

Proof. Use membership characterizations of first projection and of the lift. ?

Theorem (`InfoSys.liftLeft.sndFinset_eq`). The second projection of a left lift is contained in $\{\Delta_{\mathbf{B}}\}$.

Proof. Each token in the lift has second component $\Delta_{\mathbf{B}}$. ?

Theorem (`InfoSys.liftLeft.con`). The left lift of a consistent set v is consistent in the product system.

Proof. First projection recovers v; second projection lies in the singleton of bottom. ?

5.6.20 Pairing map

Definition (`ApproximableMap.pairMap`). For approximable mappings $f : \mathbf{C} \to \mathbf{A}$ and $g : \mathbf{C} \to \mathbf{B}$, the pairing $\langle f, g\rangle$ relates s to a product set u when s is f-related to the first projection of u and s is g-related to the second projection of u.

Theorem (`ApproximableMap.pairMap.comp_fst`). Composing the first projection after the pairing recovers f.

Proof. On relatedness, use monotonicity in the source; conversely build the pairing over a left lift and extend relatedness on the second factor using entailments into bottom. ?

Theorem (`ApproximableMap.pairMap.comp_snd`). Composing the second projection after the pairing recovers g.

Proof. Symmetric to the first projection case, using right lifts. ?

Theorem (`ApproximableMap.pairMap.unique`). An approximable mapping $h : \mathbf{C} \to \mathbf{A} \times \mathbf{B}$ whose compositions with the projections are f and g equals $\langle f, g\rangle$.

Proof. Pointwise on elements, equality of first and second components forces equality in the product by the element lemma; Proposition 5.3 finishes. ?

5.6.21 Proposition 6.2: projections and pairing

PROPOSITION 6.2. *If* $\mathbf{A}$ *and* $\mathbf{B}$ *are information systems, then so is* $\mathbf{A} \times \mathbf{B}$*, and we have mappings*

$$\mathrm{fst} : \mathbf{A} \times \mathbf{B} \to \mathbf{A} \text{ and } \mathrm{snd} : \mathbf{A} \times \mathbf{B} \to \mathbf{B},$$

such that, for approximable mappings

$$f : \mathbf{C} \to \mathbf{A} \text{ and } g : \mathbf{C} \to \mathbf{B},$$

there is one and only one approximable mapping $\langle f, g\rangle : \mathbf{C} \to \mathbf{A} \times \mathbf{B}$ *such that*

$$\mathrm{fst} \circ \langle f, g\rangle = f \text{ and } \mathrm{snd} \circ \langle f, g\rangle = g.$$

Proof. Checking that 6.1 does indeed define an information system is straightforward, but there are six things that must be proved according to Definition 2.1. We have to leave the details to the reader. Next using the notation of 6.1, where fst and snd were applied as operations on consistent sets $u \in \mathrm{Con}_{\mathbf{A}\times\mathbf{B}}$, we redefine matters to have approximable mappings, where, for $v \in \mathrm{Con}_{\mathbf{A}}$ and $w \in \mathrm{Con}_{\mathbf{B}}$,

(1) u fst v iff $\mathrm{fst}\, u \vdash_{\mathbf{A}} v$;

(2) $u \ \mathrm{snd}\ w$ iff $\mathrm{snd}\, u \vdash_{\mathbf{B}} w$; and
(3) $s \ \langle f, g\rangle \ u$ iff $s \ f \ (\mathrm{fst}\, u)$ and $s \ g \ (\mathrm{snd}\, u)$.

Because we defined $\mathbf{A} \times \mathbf{B}$ so that consistency and entailment worked independently on the two halves of the set of data objects, it is easy to check that (1)–(3) define approximable mappings having the desired properties.

The uniqueness of $\langle f, g\rangle$ comes out of the observation that, if z and z' are two elements of $\mathbf{A} \times \mathbf{B}$ for which

$$\mathrm{fst}(z) = \mathrm{fst}(z') \text{ and } \mathrm{snd}(z) = \mathrm{snd}(z'),$$

then $z = z'$. The reason is that fst and snd just divide elements into the two kinds of data objects, and then strip off the parentheses. (Look back at Definition 6.1.) No information is lost, so if z and z' are transformed into the same elements both times, then they have to be the same.

That lemma treats one pair of elements at a time, but $\langle f, g\rangle$ is a function. But if $\langle f, g\rangle'$ were another function satisfying the conditions of the above proposition, then the two functions would be pointwise equal. We could then quote 5.3 to assure ourselves that they are the same function. ■

Theorem (`ApproximableMap.proposition_6_2`). For approximable mappings $f : \mathbf{C} \to \mathbf{A}$, $g : \mathbf{C} \to \mathbf{B}$, and $h : \mathbf{C} \to \mathbf{A} \times \mathbf{B}$, if $\mathrm{fst} \circ h = f$ and $\mathrm{snd} \circ h = g$, then $h = \langle f, g\rangle$.

Proof. Uniqueness of the pairing. ?

Ordered pairs. By using the definition

$$(x, y) = \langle \mathrm{const}(x), \mathrm{const}(y)\rangle(\bot_{\mathbf{C}}),$$

which invokes 6.2 on any convenient fixed domain $\mathbf{C}$, it is easy to prove that $|\mathbf{A} \times \mathbf{B}|$ is in a one-one correspondence with the set-theoretical product of $|\mathbf{A}|$ and $|\mathbf{B}|$. Indeed, it can be shown that for $x \in |\mathbf{A}|$ and $y \in |\mathbf{B}|$,

(1) $(x, y) = \{(X, \Delta_{\mathbf{B}}) \mid X \in x\} \cup \{(\Delta_{\mathbf{A}}, Y) \mid Y \in y\} \in |\mathbf{A} \times \mathbf{B}|$;
(2) $\mathrm{fst}(x, y) = x$;
(3) $\mathrm{snd}(x, y) = y$;
and, for all $z \in |\mathbf{A} \times \mathbf{B}|$,
(4) $z = (\mathrm{fst}\, z, \mathrm{snd}\, z)$.
Also, using the notation of 6.2, we can say that
(5) $\langle f, g\rangle(t) = (f(t), g(t))$,
for all $t \in |\mathbf{C}|$.

There are also remarks that could be made about the pointwise nature of the partial ordering of $|\mathbf{A} \times \mathbf{B}|$, but we will not formulate them here. We do remark, however, that there is also a trivial product of no terms, $\mathbf{1}$, called the *unit type* or *domain*. It is such that $D_{\mathbf{1}} = \{\Delta_{\mathbf{1}}\}$, and

that equation determines it up to isomorphism. The domain $\mathbf{1}$ has but one element, namely $\bot_{\mathbf{1}}$. Note also that all approximable mappings $f : \mathbf{1} \to \mathbf{A}$ are constant, which shows how Definition 5.1 is a generalization of Definition 3.1. Note finally that there is but one approximable mapping $f : \mathbf{A} \to \mathbf{1}$, namely $f = 0 = \mathrm{const}(\bot_{\mathbf{1}})$. ■

We turn now to the definition and properties of sums of domains.

5.7.10 Left projection of sum sets

Definition (`lftFinset`). The left projection of a finite set of sum tokens collects the $\mathbf{A}$-data of left tokens.

Theorem (`mem_lftFinset`). Membership in the left projection matches a witnessing left token.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`lftFinset.empty`). The left projection of the empty set is empty.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`lftFinset.funion`). Left projection preserves finite unions.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`lftFinset.insert_bot`). Inserting bottom leaves the left projection unchanged.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`lftFinset.insert_left`). Inserting a left token adjoins its datum.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`lftFinset.insert_right`). Inserting a right token leaves the left projection unchanged.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`lftFinset.mono`). Left projection is monotone.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`lftFinset.singleton_bot`). The left projection of singleton bottom is empty.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`lftFinset.singleton_left`). The left projection of a singleton left token is that datum.

Proof. Direct from the definitions and the ambient information-system axioms. ?

5.7.12 Sum consistency

Definition (`SumCon`). A finite set of sum tokens is consistent when exactly one side is a consistent nonempty projection and the other is empty, or both projections are empty under the left-consistent clause.

Theorem (`SumCon.lft_con_of_lft_nonempty`). A nonempty left projection of a consistent sum set is consistent in $\mathbf{A}$.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`SumCon.lft_empty_of_rht_nonempty`). A nonempty right projection forces the left projection empty.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`SumCon.rht_con_of_rht_nonempty`). A nonempty right projection of a consistent sum set is consistent in $\mathbf{B}$.

Proof. Direct from the definitions and the ambient information-system axioms. ?

Theorem (`SumCon.rht_empty_of_lft_nonempty`). A nonempty left projection forces the right projection empty.

Proof. Direct from the definitions and the ambient information-system axioms. ?

5.7.14 Definition 6.3: separated sum

DEFINITION 6.3. Let $\mathbf{A}$ and $\mathbf{B}$ be two information systems. By $\mathbf{A}+\mathbf{B}$, the *separated sum system*, we understand the system where, after choosing some convenient object Δ belonging neither to $D_{\mathbf{A}}$ nor to $D_{\mathbf{B}}$, we have:

(i) $D_{\mathbf{A}+\mathbf{B}} = \{(X,\Delta) \mid X \in D_{\mathbf{A}}\} \cup \{(\Delta,Y) \mid Y \in D_{\mathbf{B}}\} \cup \{(\Delta,\Delta)\}$;

(ii) $\Delta_{\mathbf{A}+\mathbf{B}} = (\Delta,\Delta)$;

(iii) $u \in \mathrm{Con}_{\mathbf{A}+\mathbf{B}}$ iff either $\mathrm{lft}\, u \in \mathrm{Con}_{\mathbf{A}}$ and $\mathrm{rht}\, u = \emptyset$ or $\mathrm{lft}\, u = \emptyset$ and $\mathrm{rht}\, u \in \mathrm{Con}_{\mathbf{B}}$;

(iv') $u \vdash_{\mathbf{A}+\mathbf{B}} (X',\Delta)$ iff $\mathrm{lft}\, u \neq \emptyset$ and $\mathrm{lft}\, u \vdash_{\mathbf{A}} X'$;
(iv'') $u \vdash_{\mathbf{A}+\mathbf{B}} (\Delta,Y')$ iff $\mathrm{rht}\, u \neq \emptyset$ and $\mathrm{rht}\, u \vdash_{\mathbf{B}} Y'$; and
(iv''') $u \vdash_{\mathbf{A}+\mathbf{B}} (\Delta,\Delta)$ always holds,
where, in (iii), u is any finite subset of $D_{\mathbf{A}+\mathbf{B}}$, in (iv')–(iv'''), $u \in \mathrm{Con}_{\mathbf{A}+\mathbf{B}}$, and we let:

$$\mathrm{lft}\, u = \{X \in D_{\mathbf{A}} \mid (X,\Delta) \in u\}, \quad \mathrm{rht}\, u = \{Y \in D_{\mathbf{B}} \mid (\Delta,Y) \in u\}.$$

■

The plan of the sum definition is very similar to that for product, except that (1) for reasons to be made clear in examples, the parts do not share the least informative element (i.e. the data objects $(\Delta_{\mathbf{A}},\Delta)$, $(\Delta,\Delta_{\mathbf{B}})$, and (Δ,Δ) are inequivalent in this system), and (2) instead of defining consistency and entailment in a conjunctive way, these notions are defined disjunctively. The effect of these changes over Definition 6.1 is to produce a system $\mathbf{A}+\mathbf{B}$ whose elements divide into disjoint copies of those of $\mathbf{A}$ and $\mathbf{B}$ (plus an extra element $\bot_{\mathbf{A}+\mathbf{B}}$). These remarks can be made more precise in the following way:

Definition (`InfoSys.sumSystem`). The separated sum of information systems $\mathbf{A}$ and $\mathbf{B}$ is the information system whose data are the sum tokens of Definition 6.3(i), whose least informative object is the shared sum bottom (Δ, Δ), whose consistent sets are those that live entirely on the left factor or entirely on the right factor as in 6.3(iii), and whose entailment of a token is the corresponding one-sided entailment of 6.3(iv')–(iv'') (with the sum bottom always entailed). The information-system axioms hold by case analysis on sum tokens, using the left and right projections together with the consistency and entailment axioms of the occupied factor.

5.7.17 Left sum lift

Definition (`InfoSys.instLeftCommutativeLiftSumLeft`). Inserting left sum tokens is left-commutative, so finite left lifts are well-defined independently of insertion order.

Definition (`InfoSys.liftSumLeft`). The left sum lift of a finite set $v \subseteq D_{\mathbf{A}}$ is the finite set of left tokens (X, Δ) for $X \in v$.

Theorem (`InfoSys.liftSumLeft.mem_foldr`). Membership in a left sum lift built by folding insertion over a multiset equals membership of some left token over that multiset.

Proof. Induction on the multiset, using the characterization of insert membership. ?

Theorem (`InfoSys.liftSumLeft.mem`). A sum token lies in the left lift of v iff it is a left token of some $X \in v$.

Proof. Unfold the lift and apply the fold characterization. ?

Theorem (`InfoSys.liftSumLeft.lftFinset_eq`). The left projection of a left sum lift recovers the original set v.

Proof. Use the membership characterizations of left projection and of the lift. ?

Theorem (`InfoSys.liftSumLeft.rhtFinset_eq`). The right projection of a left sum lift is empty.

Proof. Every token in the lift is a left token. ?

Theorem (`InfoSys.liftSumLeft.con`). The left sum lift of a consistent set v is consistent in the separated sum.

Proof. Left projection recovers v; right projection is empty. ?

5.7.19 Sum entailment helpers

Theorem (`InfoSys.entSet.lft_of_sumEntSet`). If u entails u' in the separated sum, then the left projection of u entails the left projection of u' in $\mathbf{A}$.

Proof. Project the sum entailment along left tokens. ?

Theorem (`InfoSys.entSet.rht_of_sumEntSet`). If u entails u' in the separated sum, then the right projection of u entails the right projection of u' in $\mathbf{B}$.

Proof. Project the sum entailment along right tokens. ?

Theorem (`InfoSys.entSet.lft_eq_empty`). If the left projection of u is empty and u entails u' in the separated sum, then the left projection of u' is empty.

Proof. A left token in u' would require the left side of u to be inhabited. ?

Theorem (`InfoSys.entSet.rht_eq_empty`). If the right projection of u is empty and u entails u' in the separated sum, then the right projection of u' is empty.

Proof. A right token in u' would require the right side of u to be inhabited. ?

Theorem (`InfoSys.entSet.liftLft_of_left_only`). If u is consistent with empty right projection, then the left lift of the left projection of u entails u in the separated sum.

Proof. Consistency of the lift follows from recovering the left projection; each left token of u is entailed by reflexivity on that projection, and right tokens cannot occur. ?

Theorem (`InfoSys.entSet.liftRht_of_right_only`). If u is consistent with empty left projection, then the right lift of the right projection of u entails u in the separated sum.

Proof. Dual to the left-only case. ?

Theorem (`InfoSys.entSet.empty_of_rel_bot_like`). Let h be an approximable map from the separated sum that sends the bottom element to bottom. If u is consistent with both projections empty and h relates u to a consistent s, then the empty set entails s.

Proof. Such a u sits under the sum bottom, so the image of its closure under h sits under the codomain bottom; every member of s is therefore entailed from the empty set via the bottom token. ?

5.7.20 Sum elements

Definition (`ApproximableMap.sumLftCarrier`). The left carrier of a sum element z is the set of tokens X of $\mathbf{A}$ such that (X, Δ) lies in z.

Definition (`ApproximableMap.sumRhtCarrier`). The right carrier of a sum element z is the set of tokens Y of $\mathbf{B}$ such that (Δ, Y) lies in z.

Theorem (`ApproximableMap.not_mem_right_of_mem_left`). A sum element cannot contain both a left token and a right token.

Proof. The two-point set of those tokens would be consistent in z, contradicting separated-sum consistency. ?

Theorem (`ApproximableMap.eq_botElement_of_no_injections`). If a sum element contains neither left nor right tokens, it is the bottom element.

Proof. Only the sum bottom token can remain, and bottom is least. ?

Theorem (`ApproximableMap.subset_botElement_of_projections_empty`). A finite sum set with empty left and right projections sits inside the bottom element.

Proof. Every member must be the sum bottom token. ?

Definition (`ApproximableMap.sumElementLft`). Given a sum element z containing a left token (X_0, Δ), the left element of z is the $\mathbf{A}$-element whose carrier is the left carrier of z.

Definition (`ApproximableMap.sumElementRht`). Given a sum element z containing a right token (Δ, Y_0), the right element of z is the $\mathbf{B}$-element whose carrier is the right carrier of z.

5.7.21 Left injection map

Definition (`ApproximableMap.inlMap`). The left injection $\mathrm{inl} : \mathbf{A} \to \mathbf{A} + \mathbf{B}$ relates a consistent v to a sum set u when u is consistent with empty right projection and v entails the left projection of u.

Theorem (`ApproximableMap.inlMap.toElement_sumElementLft`). Applying the left injection's element map to the left element of a sum element z that contains a left token recovers z.

Proof. One inclusion uses left closure under the related entailment and excludes right tokens by the empty right projection; the other rebuilds relatedness from left carriers and excludes right tokens by injection separation. ?

5.7.23 Copairing map

Theorem (`InfoSys.entSet.u_of_inl_witness`). If u is consistent with nonempty left projection and empty right projection, v is left-injection-related to u', and the left projection of u entails v, then u entails u' in the separated sum.

Proof. Transfer left-factor entailment along the injection relatedness; right tokens in u' are impossible by the empty right projection of u'. ?

Theorem (`InfoSys.entSet.u_of_inr_witness`). Dual to the left witness: a right-only consistent u whose right projection entails a right-injection witness of u' entails u' in the separated sum.

Proof. Dual to the left case. ?

Theorem (`ApproximableMap.copairMap.union_disj`). The three-way disjunct that defines copair relatedness is closed under finite union of consequents: empty-entailment cases combine, same-side relatedness unions, and opposite inhabited sides are impossible.

Proof. Case analysis on the two disjuncts, using multiary union, monotonicity of f and g from the empty relation, and separated-sum side exclusion. ?

Definition (`ApproximableMap.copairMap`). For approximable mappings $f : \mathbf{A} \to \mathbf{C}$ and $g : \mathbf{B} \to \mathbf{C}$, the copairing $[f, g] : \mathbf{A} + \mathbf{B} \to \mathbf{C}$ relates a consistent sum set u to a consistent s when either the empty set entails s, or the left projection of u is inhabited and f-related to s, or the right projection of u is inhabited and g-related to s.

Theorem (`ApproximableMap.copairMap.botElement`). The element map of a copairing sends the sum bottom element to the codomain bottom element.

Proof. Related witnesses under the sum bottom can only involve the sum bottom token, so both projections are empty and the empty-entailment clause forces membership under the codomain bottom; the converse uses the empty domain set. ?

Theorem (`ApproximableMap.copairMap.comp_inl`). Composing the left injection after the copairing recovers f.

Proof. Forward, discard empty and right clauses by the empty right projection of an injection witness and apply monotonicity; conversely lift an f-related set through a left sum lift of the set with bottom adjoined. ?

Theorem (`ApproximableMap.copairMap.comp_inr`). Composing the right injection after the copairing recovers g.

Proof. Dual to the left injection case, using right sum lifts. ?

Theorem (`ApproximableMap.copairMap.unique`). An approximable mapping h from the separated sum that composes with the injections to f and g and sends bottom to bottom equals the copairing $[f, g]$.

Proof. On relatedness, classify by which projections of u are inhabited: both empty uses the bottom-like empty entailment lemma; a single inhabited side recovers f or g via the corresponding lift and composition hypothesis, then transfers back with the injection witnesses. ?

5.7.24 Proposition 6.4: injections and copairing

PROPOSITION 6.4. If $\mathbf{A}$ and $\mathbf{B}$ are information systems, then so is $\mathbf{A} + \mathbf{B}$, and we have approximable mappings

$$\mathrm{inl} : \mathbf{A} \to \mathbf{A} + \mathbf{B} \quad \text{and} \quad \mathrm{inr} : \mathbf{B} \to \mathbf{A} + \mathbf{B},$$

such that, for approximable mappings

$$f : \mathbf{A} \to \mathbf{C} \quad \text{and} \quad g : \mathbf{B} \to \mathbf{C},$$

there is one and only one approximable mapping $[f, g] : \mathbf{A} + \mathbf{B} \to \mathbf{C}$, such that

$$[f, g] \circ \mathrm{inl} = f, \quad [f, g] \circ \mathrm{inr} = g, \quad \text{and} \quad [f, g](\bot_{\mathbf{A}+\mathbf{B}}) = \bot_{\mathbf{C}} .$$

Proof. The proof that 6.3 defines a system satisfying the basic axioms of 2.1 has to be left to the reader. Next using the notation of 6.1, where lft and rht were applied as operations on consistent sets $u \in \mathrm{Con}_{\mathbf{A}+\mathbf{B}}$, we redefine matters to have approximable mappings, where, for $v \in \mathrm{Con}_{\mathbf{A}}$ and $w \in \mathrm{Con}_{\mathbf{B}}$,

(1) v inl u iff $\{(X, \Delta) \mid X \in v\} \vdash_{\mathbf{A}+\mathbf{B}} u$;

(2) w inr u iff $\{(\Delta, Y) \mid Y \in w\} \vdash_{\mathbf{A}+\mathbf{B}} u$; and

(3) $u\ [f, g]\ s$ iff either $\vdash_{\mathbf{C}}\ s$, or $\mathrm{lft}\, u \neq \emptyset$ and $\mathrm{lft}\, u\ f\ s$, or $\mathrm{rht}\, u \neq \emptyset$ and $\mathrm{rht}\, u\ g\ s$.

Because we defined $\mathbf{A}+\mathbf{B}$ so that consistency and entailment worked on the two halves of the set of data objects just as they worked on $\mathbf{A}$ and $\mathbf{B}$, respectively, it is easy to check that (1)–(3) define approximable mappings, and that the desired properties hold.

The uniqueness of $[f, g]$ comes from the fact that the elements of $\mathbf{A} + \mathbf{B}$, apart from the bottom element of the domain, are just the elements in the ranges of inl and inr. Since the function $[f, g]$ takes bottom to bottom (in the indicated domains), it will be uniquely determined by what it does on the two halves of the sum. The last equations of the theorem just say that the function is completely determined on these elements. ■

It can also be shown that Propositions 6.2 and 6.4 uniquely characterize the domains $\mathbf{A} \times \mathbf{B}$ and $\mathbf{A} + \mathbf{B}$ up to isomorphism, and they give us the existence of additional mappings that are needed to show that product and sum are functors on the category of domains. We can also show from these results that the domain

$$\mathbf{BOOL} = \mathbf{1} + \mathbf{1}$$

has two elements true and false, such that any mapping on $\mathbf{BOOL}$ is uniquely determined by its action on true, false and $\bot_{\mathbf{BOOL}}$, and the values on the first two elements may be arbitrarily chosen.

Theorem (`ApproximableMap.proposition_6_4`). For approximable mappings $f : \mathbf{A} \to \mathbf{C}$, $g : \mathbf{B} \to \mathbf{C}$, and $h : \mathbf{A} + \mathbf{B} \to \mathbf{C}$, if $h \circ \mathrm{inl} = f$, $h \circ \mathrm{inr} = g$, and $h(\bot_{\mathbf{A}+\mathbf{B}}) = \bot_{\mathbf{C}}$, then $h = [f, g]$.

Proof. Apply uniqueness of the copairing. ?

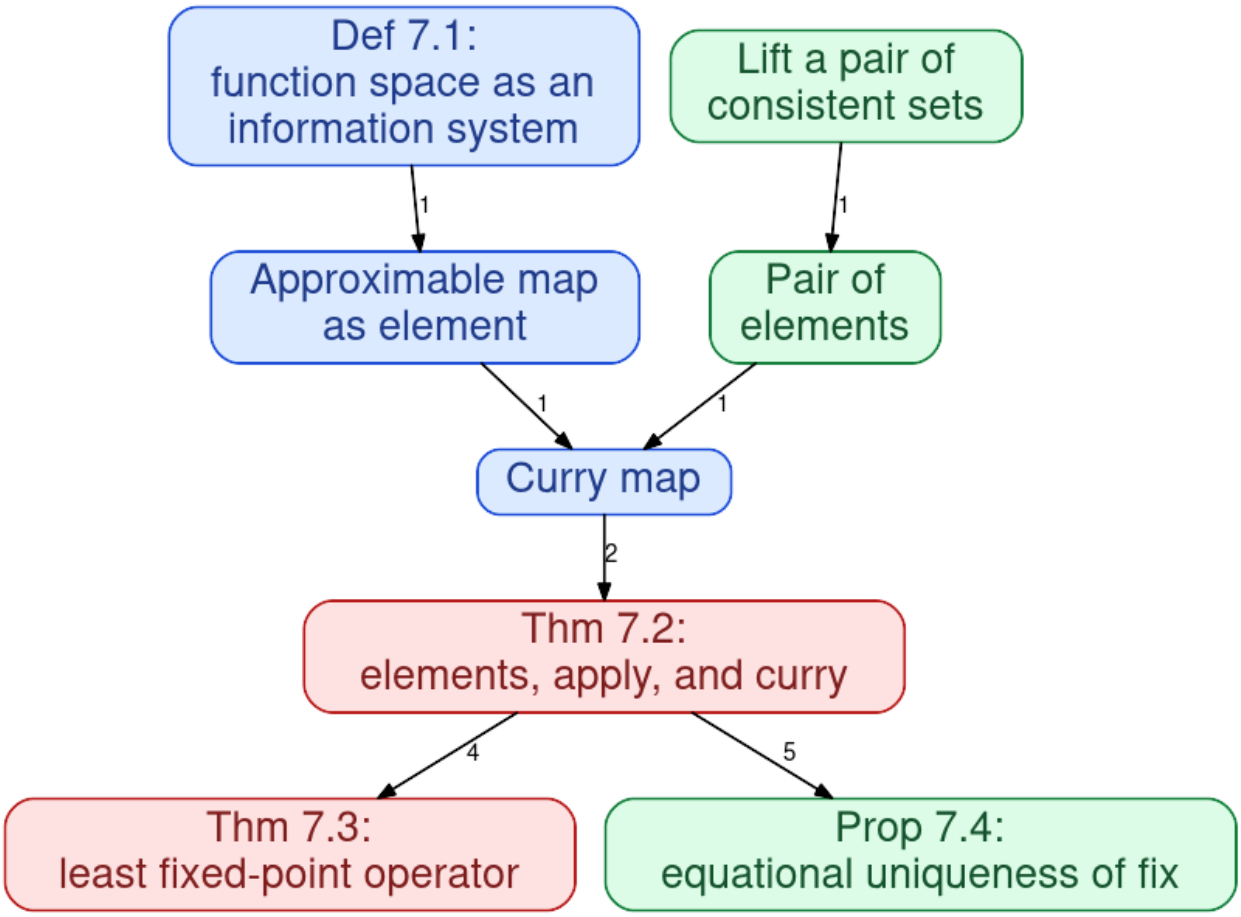

Figure 61: Diagram 26

5.8.1 Introduction

Functions or mappings between domains are of basic importance for our theory, since it is through them that we most easily transform data and relate the structures into which the elements defined by the data objects enter. There are many possible functions, and large groups of them can be treated in a uniform manner. For instance, if the source and target domains match properly, any pair of functions can be composed—composition is an operation on functions of general significance. Now, if in the theory we could combine functions into domains themselves, then an operation like composition might become a mapping of the theory. Indeed, this is exactly what happens: suitably construed, composition is an approximable mapping of two arguments. Of course, for each configuration of linked source and target domains, there is a separate composition operation.

In order to make approximable mappings elements of a suitable domain, we have to discover first what their appropriate data objects are. In Section 5 this was hinted at already. To determine an approximable mapping $f : \mathbf{A} \to \mathbf{B}$, we have to say which pairs (u, v) with $u \in D_{\mathbf{A}}$ and $v \in D_{\mathbf{B}}$ stand in the mapping relation $u\ f\ v$. One such pair gives a certain (finite) amount of information about the possible functions that contain it, and an approximable mapping is completely determined by such pairs. Therefore, if there are appropriate notions of consistency and entailment for these pairs, we will be able to form a domain having

functions as elements. Let us try out a formal definition first, and then look to an explanation of how it works.

5.8.2 Definition 7.1: function space as an information system

DEFINITION 7.1. Let $\mathbf{A}$ and $\mathbf{B}$ be two information systems. By $\mathbf{A} \to \mathbf{B}$, the *function space*, we understand the system where:

(i) $D_{\mathbf{A}\to\mathbf{B}} = \{(u, v) \mid u \in \mathrm{Con}_{\mathbf{A}} \text{ and } v \in \mathrm{Con}_{\mathbf{B}}\}$;

(ii) $\Delta_{\mathbf{A}\to\mathbf{B}} = (\emptyset, \emptyset)$; and where,

for all n and all $w = \{(u_0, v_0), \ldots, (u_{n-1}, v_{n-1})\}$, we have:

(iii) $w \in \mathrm{Con}_{\mathbf{A}\to\mathbf{B}}$ iff whenever $I \subseteq \{0, \ldots, n-1\}$ and $\bigcup\{u_i \mid i \in I\} \in \mathrm{Con}_{\mathbf{A}}$, then $\bigcup\{v_i \mid i \in I\} \in \mathrm{Con}_{\mathbf{B}}$; and

(iv) $w \vdash_{\mathbf{A}\to\mathbf{B}} (u', v')$ iff $\bigcup\{v_i \mid u' \vdash_{\mathbf{A}} u_i\} \vdash_{\mathbf{B}} v'$,

for all $u' \in \mathrm{Con}_{\mathbf{A}}$ and $v' \in \mathrm{Con}_{\mathbf{B}}$. ■

We have already explained the choice of data objects in (i) above, and the least informative pair in (ii) is clearly right. Remember that as a data object (u, v) should be read as meaning that if the information in u is supplied as input, then at least v will be obtained as output. It is pretty obvious that one such data object by itself is consistent (they make constant functions, don't they?), but a set of several of these pairs may not be consistent. Hence, the need for part (iii) of the definition. It can be read informally as follows: Look for a selection I of the indices used in setting up w where the u_i for $i \in I$ are jointly consistent. Since the pairs in w are meant as correct information about a single function, then the combined input from all these selected u_i must be allowable. The function will then be required to give as output at least all the v_i for $i \in I$, owing to the fact that we are given that w is true of the function we have in mind. As a consequence, the set $\bigcup\{v_i \mid i \in I\}$ has got to be consistent, because it comes as output from consistent input for a single approximable function. What we are arguing for is the necessity of (iii)—the word "consistency" should mean that the data objects in the set are all true of at least one function.

Finally we have to argue that (iv) must give the right notion of entailment for these data objects. This can be seen by noting that for a fixed consistent w the set of pairs (u', v') satisfying the right-hand side of (iv) defines an approximable function. In checking this we have to remark that, for each $u' \in \mathrm{Con}_{\mathbf{A}}$, the set $\bigcup\{v_i \mid u' \vdash_{\mathbf{A}} u_i\}$ is consistent, so the definition makes sense. The transitivity properties needed for proving that we have an approximable mapping are easy to establish. This shows in particular that w is true of at least one approximable function, since the separate pairs (u_i, v_i) all satisfy the definition. But it is also simple to argue that for any approximable function, if w is true of it, then so is any pair (u', v') satisfying the definition of (iv). Consequently, what we find in (iv) is the definition of the least approximable function generated by w. The argument we have just outlined thus shows that the relationship $w \vdash_{\mathbf{A}\to\mathbf{B}} (u', v')$ means exactly that whenever w is true of an approximable mapping then so is (u', v'). It follows at once that $\vdash_{\mathbf{A}\to\mathbf{B}}$ is an entailment relation, and that the elements of $\mathbf{A} \to \mathbf{B}$ are just the approximable mappings, as we indicate in the next theorem.

Theorem (`functionSystem.con_sing`). A singleton set of fun tokens is consistent.

Proof. Any subset is empty or the singleton; the output union of a nonempty selection is contained in the singleton output, so consistency of that output applies. ?

Theorem (`functionSystem.con_subset`). Consistency of fun-token sets is downward closed under inclusion.

Proof. A subset of a selection from a smaller set is a selection from the larger set. ?

Theorem (`functionSystem.ent_bot`). Every consistent set of fun tokens entails the function-space bottom.

Proof. Take the empty witness subset; both entailment conditions are vacuous. ?

Theorem (`functionSystem.ent_con`). If a consistent set entails a fun token, then adjoining that token preserves consistency.

Proof. For a selection that avoids the new token, appeal to the original consistency. For a selection that includes it, delete the token, combine its input with the remaining input union via the entailment witness, and transport consistency of the combined outputs back through finite-union algebra and the insert lemmas for input and output unions. ?

Theorem (`functionSystem.ent_refl`). A consistent set entails each of its own tokens.

Proof. The singleton witness consisting of that token, with reflexivity of entailment on each side. ?

Theorem (`functionSystem.ent_trans`). Fun entailment is transitive: if every token of u is entailed by v and u entails c, then v entails c.

Proof. Combine the per-token witnesses into a single witness by the combined-witness lemma, then compose the output entailments. ?

Definition (`InfoSys.functionSystem`). The function space $\mathbf{A} \to \mathbf{B}$ is the information system whose data are the fun tokens of Definition 7.1(i), whose least informative object is the function-space bottom $(\emptyset, \emptyset)$, whose consistent sets are those satisfying Definition 7.1(iii), and whose entailment is Definition 7.1(iv). The information-system axioms hold by the six lemmas above.

Definition (`FunToken`). A fun token of information systems $\mathbf{A}$ and $\mathbf{B}$ is a pair of consistent finite sets (u, v) with u consistent in $\mathbf{A}$ and v consistent in $\mathbf{B}$.

Definition (`instDecidableEqFunToken`). Fun tokens have decidable equality, decided componentwise on the two finite sets.

Theorem (`funBot.property`). The empty finite set is consistent in every information system, on both the input and output sides.

Proof. Empty consistency of each factor. ?

Definition (`funBot`). The least informative fun token is the pair of empty sets $(\emptyset, \emptyset)$.

Definition (`instLeftCommutativeFunInput`). Inserting an input component into the accumulated input union is left-commutative, so multiset folds over input components are independent of order.

Definition (`instLeftCommutativeFunOutput`). Inserting an output component into the accumulated output union is left-commutative, so multiset folds over output components are independent of order.

Theorem (`mem_foldr_funInput`). An element lies in the fold of input-component union over a multiset of fun tokens precisely when it lies in the input of some token of the multiset.

Proof. Induction on the multiset, using membership for finite union at each cons step. ?

Theorem (`mem_foldr_funOutput`). An element lies in the fold of output-component union over a multiset of fun tokens precisely when it lies in the output of some token of the multiset.

Proof. Induction on the multiset, using membership for finite union at each cons step. ?

Definition (`funInputUnion`). The input union of a finite set of fun tokens is the finite union of their input components, obtained by folding finite union over the underlying multiset.

Theorem (`funInputUnion.empty`). The input union of the empty set is empty.

Proof. The fold over the empty multiset returns the empty seed. ?

Theorem (`mem_funInputUnion`). Membership in the input union is membership in the input of some token of the set.

Proof. The fold membership characterisation for inputs. ?

Theorem (`entSet_inputUnion_of_ent`). If a consistent set entails every input component of a finite set of fun tokens, then it entails their input union.

Proof. Unpack membership in the input union and apply the given entailments. ?

Theorem (`funInputUnion.con_of_ent`). The input union of a set of fun tokens whose inputs are all entailed by a consistent set is itself consistent.

Proof. Form the finite union of the witnessing set with the input union and use subset closure of consistency. ?

Theorem (`funInputUnion.funion`). Input union preserves finite unions of token sets.

Proof. Compare membership on both sides via membership in the input union and in a finite union. ?

Theorem (`funInputUnion.singleton`). The input union of a singleton is the input of that token.

Proof. Membership in the input union collapses to the unique token. ?

Theorem (`funInputUnion.insert`). Inserting a token adjoins its input to the input union.

Proof. Rewrite insert as a finite union with a singleton and apply the union and singleton lemmas. ?

Definition (`funOutputUnion`). The output union of a finite set of fun tokens is the finite union of their output components, obtained by folding finite union over the underlying multiset.

Theorem (`funOutputUnion.empty`). The output union of the empty set is empty.

Proof. The fold over the empty multiset returns the empty seed. ?

Theorem (`mem_funOutputUnion`). Membership in the output union is membership in the output of some token of the set.

Proof. The fold membership characterisation for outputs. ?

Theorem (`funOutputUnion.funion`). Output union preserves finite unions of token sets.

Proof. Compare membership on both sides via membership in the output union and in a finite union. ?

Theorem (`funOutputUnion.singleton`). The output union of a singleton is the output of that token.

Proof. Membership in the output union collapses to the unique token. ?

Theorem (`funOutputUnion.insert`). Inserting a token adjoins its output to the output union.

Proof. Rewrite insert as a finite union with a singleton and apply the union and singleton lemmas. ?

Definition (`FunCon`). A finite set w of fun tokens is consistent when every subset whose input union is consistent in $\mathbf{A}$ has output union consistent in $\mathbf{B}$.

Theorem (`exists_combined_witness`). Given a consistent set v of fun tokens and a finite set s of tokens whose inputs are all entailed by a fixed consistent u', together with, for each token of s, a witness subset of v that realises the fun-entailment input and output conditions for that token, there is a single subset $S \subseteq v$ whose tokens are all input-entailed by u' and whose output union entails the output union of s.

Proof. Induction on s: the empty case takes the empty witness; the insert step unions the inductive witness with the witness for the newly inserted token and reassembles the output entailment by finite-union and consistency of fun sets. ?

Definition (`FunEnt`). A consistent finite set w of fun tokens entails a fun token (u', v') when there is a subset $s \subseteq w$ such that u' entails every input of a token in s and the output union of s entails v'.

Theorem (`filter_ne_subset_of_subset_insert`). If a finite set of fun tokens is contained in the insert of p into w, then deleting p from it yields a subset of w.

Proof. Any surviving element lies in the insert and is unequal to p, hence lies in w. ?

Theorem (`insert_filter_ne`). Reinserting an element after deleting it from a finite set that contains it recovers the original set.

Proof. Compare membership on both sides by cases on equality with the deleted element. ?

5.8.3 Lift a pair of consistent sets

Definition (`liftPair`). The product lift of consistent sets u and v is the finite union of the left lift of u with the right lift of v.

Theorem (`ProdCon_liftPair`). The product lift of two consistent sets is product-consistent.

Proof. Left and right projections of the lift reduce to the given consistent sets (up to bottoms). ?

Theorem (`fstFinset_liftPair`). The first projection of a product lift is the first set united with the first projection of the right lift.

Proof. Expand the lift as a finite union and apply first-projection lemmas. ?

Theorem (`sndFinset_liftPair`). The second projection of a product lift is the second projection of the left lift united with the second set.

Proof. Expand the lift as a finite union and apply second-projection lemmas. ?

Theorem (`entSet_liftPair`). Product entailment of a lift follows from factor entailments of its components.

Proof. Lift the two entailments through the left and right embeddings and unite. ?

Theorem (`liftLeft_funion`). Left lift preserves finite unions.

Proof. Compare membership on both sides. ?

Theorem (`liftRight_funion`). Right lift preserves finite unions.

Proof. Compare membership on both sides. ?

5.8.4 Pair of elements

Definition (`pairElements`). The paired element of $x \in |\mathbf{A}|$ and $y \in |\mathbf{B}|$ consists of those product tokens whose non-bottom sides lie in the corresponding factors.

Theorem (`fstMap_pairElements`). Projecting a paired element on the left recovers the first factor.

Proof. Compare the two elements by chasing product tokens through the first projection map. ?

Theorem (`sndMap_pairElements`). Projecting a paired element on the right recovers the second factor.

Proof. Compare the two elements by chasing product tokens through the second projection map. ?

Theorem (`mem_fst_of_subset_pairElements`). Tokens of a finite set contained in a paired element have first components in the first factor whenever the second component is bottom.

Proof. Unfold membership in the paired element. ?

Theorem (`mem_snd_of_subset_pairElements`). Tokens of a finite set contained in a paired element have second components in the second factor whenever the first component is bottom.

Proof. Unfold membership in the paired element. ?

Theorem (`subset_pairElements_liftLeft`). The left lift of a finite set contained in the first factor lies in the paired element.

Proof. Left-lifted tokens have bottom on the right and first component in the first factor. ?

Theorem (`subset_pairElements_liftRight`). The right lift of a finite set contained in the second factor lies in the paired element.

Proof. Right-lifted tokens have bottom on the left and second component in the second factor. ?

Theorem (`subset_pairElements_liftPair`). The product lift of finite sets from each factor lies in the paired element.

Proof. Unite the left- and right-lift inclusions. ?

5.8.5 Approximable map as element

Theorem (`approxMap_toElement.closed`). The set of fun tokens related by an approximable map is closed under function-space entailment.

Proof. Unpack entailment witnesses and apply monotonicity and transitivity of the underlying relation. ?

Theorem (`approxMap_toElement.consistent`). The set of fun tokens related by an approximable map is consistent in the function space.

Proof. Apply fun-consistency of approximable maps to any finite subset. ?

Definition (`approxMap_toElement`). The element of $\mathbf{A} \to \mathbf{B}$ associated to an approximable map f is the set of all fun tokens (u, v) with $u\ f\ v$.

Definition (`mkFunToken`). Given consistent finite sets u and v in $\mathbf{A}$ and $\mathbf{B}$ respectively, their fun token is the pair (u, v) as a data object of the function space.

Theorem (`mkFunToken.property`). The two components of a fun token constructed from consistent sets are consistent.

Proof. Immediate from the given consistency hypotheses. ?

Theorem (`mkFunToken.eq`). Rebuilding a fun token from its components recovers the original token.

Proof. The underlying pair is unchanged. ?

Theorem (`rel_input_output_union`). If an approximable map relates every token of a finite set and the input union is consistent, then it relates the input union to the output union.

Proof. Iterate the right-union axiom of approximable maps. ?

Theorem (`funCon_of_approxMap`). Any finite set of fun tokens whose pairs all lie in an approximable relation is consistent in the function space.

Proof. For a selection whose input union is consistent, the relation's right-union and domain axioms yield consistency of the output union. ?

Theorem (`element_toApproxMap.empty_rel`). Every function-space element relates the empty input to the empty output.

Proof. The function-space bottom lies in every element. ?

Theorem (`element_toApproxMap.mono`). The relation extracted from a function-space element is monotone in both coordinates.

Proof. Use function-space entailment to strengthen inputs and weaken outputs inside the element. ?

Theorem (`element_toApproxMap.rel_cod`). Related outputs are consistent.

Proof. Membership of a fun token forces consistency of its output. ?

Theorem (`element_toApproxMap.rel_dom`). Related inputs are consistent.

Proof. Membership of a fun token forces consistency of its input. ?

Theorem (`element_toApproxMap.union_right`). The extracted relation is closed under finite union on the right.

Proof. Combine tokens via function-space consistency and entailment. ?

Definition (`element_toApproxMap`). The approximable map associated to a function-space element relates u to v precisely when the fun token (u, v) lies in the element.

Theorem (`element_toApproxMap.approxMap_toElement`). Passing from an approximable map to its element and back recovers the original map.

Proof. Compare relations pointwise via membership in the associated element. ?

Theorem (`mem_approxMap_toElement`). A fun token lies in the element of an approximable map precisely when the map relates its input to its output.

Proof. Unfold the carrier of the associated element. ?

Theorem (`approxMap_toElement_element_toApproxMap`). Passing from a function-space element to its approximable map and back recovers the original element.

Proof. Compare carriers via the membership characterisation of the associated element. ?

Theorem (`elements_equiv_approxMaps`). Approximable maps from $\mathbf{A}$ to $\mathbf{B}$ are in bijection with elements of $\mathbf{A} \to \mathbf{B}$: each direction of the round-trip is the identity.

Proof. Assemble the two round-trip lemmas for maps and for elements. ?

5.8.6 Curry map

Definition (`curryMap`). The curry of a map $h : \mathbf{A} \times \mathbf{B} \to \mathbf{C}$ relates u to a finite set s of fun tokens when u is consistent and h relates the lift of u with each input of a token in s to that token's output.

Theorem (`rel_of_funTokens`). A map out of a product that relates a fixed left component to each token of a finite set of fun tokens relates that left component paired with the input union to the output union.

Proof. Assemble the product lifts and apply the map's union and monotonicity axioms. ?

Theorem (`funCon_of_curry_pointwise`). For a fixed consistent left component, the set of fun tokens related pointwise by a product map is consistent in the function space.

Proof. Reduce a consistent input selection to a product relation and invoke consistency of the product map's outputs. ?

Definition (`applyMap`). Application is the approximable map from $(\mathbf{B} \to \mathbf{C}) \times \mathbf{B}$ to $\mathbf{C}$ that relates a product-consistent set s to t when the function-space entailment encoded by s yields t from the second projection.

Theorem (`applyMap_toElement`). Evaluating apply at a paired element (g, y) recovers the application $g(y)$ of the approximable map associated to g.

Proof. Chase membership through apply, pairing, and the element–map round-trips. ?

Definition (`uncurryMap`). The uncurry of a map into a function space is apply composed with pairing against the identity on the left factor.

Theorem (`uncurry_curryMap`). Uncurry after curry recovers the original product map.

Proof. Compare relations by unpacking curry's pointwise condition against apply of the paired lifts. ?

Theorem (`curryMap_unique`). If uncurry of k equals h, then k equals the curry of h.

Proof. From the universal property of uncurry–curry, compare k to curry h via the round-trip. ?

5.8.7 Theorem 7.2: elements, apply, and curry

THEOREM 7.2. If $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are information systems, then so is $\mathbf{A} \to \mathbf{B}$, and the approximable mappings $f : \mathbf{A} \to \mathbf{B}$ are exactly the elements $f \in |\mathbf{A} \to \mathbf{B}|$. Moreover we have an approximable mapping apply : $(\mathbf{B} \to \mathbf{C}) \times \mathbf{B} \to \mathbf{C}$ such that whenever $g : \mathbf{B} \to \mathbf{C}$ and $y \in |\mathbf{B}|$, then

$$\text{apply}(g, y) = g(y).$$

Furthermore, for all approximable mappings $h : \mathbf{A} \times \mathbf{B} \to \mathbf{C}$, there is one and only one approximable mapping curry $h : \mathbf{A} \to (\mathbf{B} \to \mathbf{C})$ such that

$$h = \text{apply} \circ \langle (\text{curry } h) \circ \text{fst}, \text{snd} \rangle.$$

Proof. We have already remarked on the essentials of the proof above. Definition 7.1 was devised to characterize exactly in $\text{Con}_{\mathbf{A}\to\mathbf{B}}$ the finite subsets of approximable functions, which, as binary relations, are being regarded as sets of ordered pairs. If $f : \mathbf{A} \to \mathbf{B}$ and if $w \subseteq f$, then from the properties of approximable functions, it can be checked directly that w satisfies the right-hand side of 7.1(iii). Conversely, if $w \in \text{Con}_{\mathbf{A}\to\mathbf{B}}$, then, as we have said, the relation which is defined by 7.1(iv) and may be notated by:

$$\overline{w} = \{(u', v') \mid w \vdash_{\mathbf{A}\to\mathbf{B}} (u', v')\},$$

is an approximable mapping, as can be proved using the right-hand side of 7.1(iv) and the usual properties of $\vdash_{\mathbf{A}}$ and $\vdash_{\mathbf{B}}$. Since $w \subseteq \overline{w}$, we see that $w \vdash_{\mathbf{A}\to\mathbf{B}} w'$ if, and only if, for all approximable $f : \mathbf{A} \to \mathbf{B}$, $w \subseteq f$ implies $w' \subseteq f$. (This is also the same as $w' \subseteq \overline{w}$, of course.) From these considerations it follows that not only is $\mathbf{A} \to \mathbf{B}$ an information system, but all approximable mappings are elements. Finally, if $f \in |\mathbf{A} \to \mathbf{B}|$, then—as a binary relation—it must be an approximable mapping, because the properties of Definition 5.1 are built into 7.1.

The construction of the special mapping apply as an approximable mapping also uses the idea of 7.1(iv). The consistent sets of the compound space $(\mathbf{B} \to \mathbf{C}) \times \mathbf{B}$ are essentially pairs of consistent sets, say $w \in \text{Con}_{\mathbf{B}\to\mathbf{C}}$ and $u' \in \text{Con}_{\mathbf{B}}$. Now the relation we want from such pairs to consistent sets $v' \in \text{Con}_{\mathbf{C}}$ is just nothing more or less than $w \vdash_{\mathbf{B}\to\mathbf{C}} (u', v')$. Our discussion in the previous paragraph hints at why apply does in fact reproduce functional application when we evaluate apply(g, y).

The definition of curry h uses the same trick of regarding a binary relation with one term in a relationship being a pair as corresponding to another relation with one coordinate of the pair shifted to the other side. Specifically, we can think of an approximable mapping $h : \mathbf{A} \times \mathbf{B} \to \mathbf{C}$ as a relation from pairs (u, v) of consistent sets for $\mathbf{A}$ and $\mathbf{B}$, respectively, over to consistent sets w for $\mathbf{C}$. What we want for curry h is the relationship that goes from u to the pair (v, w). Of course (v, w) is just one data object for $\mathbf{B} \to \mathbf{C}$, but the input/output passage from the consistent sets of $\mathbf{A}$ to these objects is sufficient to determine curry h as an approximable mapping. The exact connection between the two mappings is given in terms of function values as follows:

$$h(x, y) = (\text{curry } h)(x)(y),$$

for all $x \in |\mathbf{A}|$ and $y \in |\mathbf{B}|$. From this equation it follows that curry h is uniquely determined. But, from what we know about apply, this is actually the same equation as that stated at the end of the theorem. ■

Approximations to functions. Why have approximable functions been given this name? In general, elements of domains are the limits of their finite approximations. We have just indicated why the approximable

mappings from one domain into another do form the elements of a domain themselves. We have explicitly shown how to construct the finite approximable mappings $\overline{w}$. A closer examination of the definitions would emphasize the very constructive nature of this analysis. It follows that the approximable mappings can therefore be approximated by simple functions. It does not follow that all approximable mappings are simple or constructive, since what takes place in the limiting process can be very complex. But the result does show how we can start to make distinctions once a precise sense of approximation is uncovered. ■

Higher-type functions and the combinators. In the above discussion we have already combined the function-space construction with other domains by means of products. But there is nothing now stopping us from iterating the arrow domain constructor with itself as much as we like. This is how the so-called higher types are formed. In certain categories, such as the category of sets, this is a non-constructive move leading to the higher cardinal numbers. In the category of domains, however, the construct is constructive, because we have shown how to define all the parts of $\mathbf{A} \to \mathbf{B}$ in terms of very finite data objects (assuming, it need hardly be added, that $\mathbf{A}$ and $\mathbf{B}$ are constructively given).

Once the higher types have been formed as spaces, it must be asked what we are to do with them. The answer is that there are many, many mappings between these spaces that can be defined in terms of the simple notions we have been working with. These mappings are useful for the following reason: the higher types provide remarkable scope for modelling notions (as those needed in denotational semantics for example), but the various aspects of the models have to be related—and this is where these mappings come into play. We have already seen a preliminary example in the last theorem, which can be interpreted as saying why the two domains shown are isomorphic:

$$\mathbf{A} \times \mathbf{B} \to \mathbf{C} \cong \mathbf{A} \to (\mathbf{B} \to \mathbf{C}).$$

We have neither the time nor the space to present a full theory of higher-type operators here, so some further examples will have to suffice. First, we have already made use of constant mappings. Since the construction of them is very uniform, there ought to be an associated operator. In fact, we have already been using it notationally. We have the approximable mapping const : $\mathbf{B} \to (\mathbf{A} \to \mathbf{B})$ that takes every element of $\mathbf{B}$ to the corresponding constant function. (It has to be checked that this is an approximable mapping.) Note that there is a different mapping for each pair of domains $\mathbf{A}$ and $\mathbf{B}$, because the resulting types of const are different.

As another example, take the pairing of functions explained in Proposition 6.2. We can think of the operator in this case being

$$\text{pair} : (\mathbf{C} \to \mathbf{A}) \times (\mathbf{C} \to \mathbf{B}) \to (\mathbf{C} \to (\mathbf{A} \times \mathbf{B})),$$

where for functions of the proper type we have:

$$\text{pair}(f, g) = \langle f, g \rangle$$

There will be a similar operator for the construct of Proposition 6.4.

Of course the most basic operator of function composition is also approximable of the appropriate type. We can write:

$$\text{comp} : (\mathbf{B} \to \mathbf{C}) \times (\mathbf{A} \to \mathbf{B}) \to (\mathbf{A} \to \mathbf{C}),$$

where for functions of the right types we have:

$$\text{comp}(g, f) = g \circ f.$$

The approximability has to be checked, of course. But once a number of the more primitive operators have been established as being approximable, then others can be proved to be so by writing them as combinations of previously obtained operators. ■

Categories again. All of what we have been saying about operators ties in with category theory very nicely—as the category theorists have known for a long time. The technical term for what we have been doing in part is cartesian closed category—that is a property of the category of domains. Without going into details, that is essentially what 6.2 and 7.2 show of our category. But domains have many other properties beyond being a cartesian closed category. For example the possibility of forming sums is an extra (and useful) bonus, and there are many others. Nevertheless, the categorical viewpoint is a good way of organizing the properties, and it suggests other things to look for from our experiences with other categories. The next result gives a particularly important notion that can be expressed as an operator. ■

Theorem (`theorem_7_2`). For information systems $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$: the elements of $\mathbf{A} \to \mathbf{B}$ are precisely the approximable maps $f : \mathbf{A} \to \mathbf{B}$ (the two round-trips between elements and approximable maps are identities); there is an approximable map $\mathrm{apply} : (\mathbf{B} \to \mathbf{C}) \times \mathbf{B} \to \mathbf{C}$ such that $\mathrm{apply}(g, y) = g(y)$ for $g \in |\mathbf{B} \to \mathbf{C}|$ and $y \in |\mathbf{B}|$; and for every approximable $h : \mathbf{A} \times \mathbf{B} \to \mathbf{C}$ there is a unique approximable $\mathrm{curry}\, h : \mathbf{A} \to (\mathbf{B} \to \mathbf{C})$ with $h = \mathrm{uncurry}(\mathrm{curry}\, h)$, equivalently $h = \mathrm{apply} \circ \langle (\mathrm{curry}\, h) \circ \mathrm{fst}, \mathrm{snd} \rangle$.

Proof. The element–map bijection is the mutual inverse of viewing an approximable map as a function-space element and extracting the relation from an element; evaluation of apply is the paired-element lemma; uniqueness of curry and the identity $\mathrm{uncurry} \circ \mathrm{curry}$ are the corresponding library facts. ?

5.8.8 Theorem 7.3: least fixed-point operator

THEOREM 7.3. Let $\mathbf{A}$ be an information system. Then there is a unique operator, the **least fixed-point operator**, such that

(i) $\mathrm{fix} : (\mathbf{A} \to \mathbf{A}) \to \mathbf{A}$; and,

for all approximable mappings $f : \mathbf{A} \to \mathbf{A}$, we have:

(ii) $f(\mathrm{fix}(f)) \subseteq \mathrm{fix}(f)$; and

(iii) for all $x \in |\mathbf{A}|$, if $f(x) \subseteq x$, then $\mathrm{fix}(f) \subseteq x$.

Moreover, for this operator, condition (ii) is an equality.

Proof. This is a well-known result—especially the fact that the conditions above uniquely determine the operator. The only question is the existence of the operator. The inclusion of condition (ii) gives the hint, for $\mathrm{fix}(f)$ is the least solution of $f(x) \subseteq x$. Suppose x is any such element, then if $u \subseteq x$ and $u\ f\ v$ hold, it follows that $v \subseteq x$. Now, since $\emptyset \subseteq x$ always holds, if we wish to form the least x, we start with $\emptyset$ and just follow it under the action of f.

Specifically, we define $\mathrm{fix}(f)$ to be the union of all $v \in \mathrm{Con}_{\mathbf{A}}$ for which there exist a sequence $u_0, \ldots, u_n \in \mathrm{Con}_{\mathbf{A}}$ where:

(1) $u_0 = \emptyset$;

(2) $u_i\ f\ u_{i+1}$ for all $i < n$; and

(3) $u_n = v$.

Because f is approximable, it is clear that fix f is closed under entailment. To prove that it is consistent, suppose both v and v' belong to the sets thrown into the union. We have to show that $v \cup v'$ is consistent and also is thrown in. Consider the two sequences $u_0, \ldots, u_n \in \mathrm{Con}_{\mathbf{A}}$ and $u'_0, \ldots, u'_n \in \mathrm{Con}_{\mathbf{A}}$ that are responsible for putting v and v' in. It is without loss of generality that we assume they are of the same length, since we can always add lots of $\emptyset$'s onto the front of the shorter one and still satisfy (1)–(3). Now one just argues by induction on i that the sequence of unions $u_i \cup u'_i$ satisfies (1)–(3) with respect to $v \cup v'$.

But why is fix approximable? The method of proof is to replace f by $\bar{w}$ in (2) above, and to use the condition that there exists a sequence satisfying (1)–(3) as defining a relation between sets $w \in \mathrm{Con}_{\mathbf{A} \to \mathbf{A}}$

and sets $v \in \mathrm{Con}_{\mathbf{A}}$. It is not difficult to prove that this is an approximable mapping in the sense of the official definition. Clearly this relation determines fix as an operator. ■

The result above not only proves that every approximable mapping of the form $f : \mathbf{A} \to \mathbf{A}$ has a fixed point as an element of $\mathbf{A}$, but that the association of the least fixed point is itself an approximable operator. The formulation makes essential use of the partial ordering of the domains, but Gordon Plotkin noticed as an exercise that the characterization of the operator can be given entirely by equations.

Theorem (`theorem_7_3`). There is a least fixed-point operator $\mathrm{fix} : (\mathbf{A} \to \mathbf{A}) \to \mathbf{A}$ such that $f(\mathrm{fix}(f)) = \mathrm{fix}(f)$, $\mathrm{fix}(f)$ is least among pre-fixed points of f, and any operator with the pre-fixed and leastness properties equals this fix map.

Proof. Invoke equality of f at the constructed fixed point, leastness among pre-fixed points, and uniqueness of the fix map among operators with those properties. ?

5.8.9 Proposition 7.4: equational uniqueness of fix

PROPOSITION 7.4. *The least fixed-point operator is uniquely determined by the following three conditions:*

(i) $\mathrm{fix}_{\mathbf{A}} : (\mathbf{A} \to \mathbf{A}) \to \mathbf{A}$, *for all systems* $\mathbf{A}$;

(ii) $\mathrm{fix}_{\mathbf{A}}(f) = f(\mathrm{fix}_{\mathbf{A}}(f))$, *for all* $f : \mathbf{A} \to \mathbf{A}$; *and*

(iii) $h(\mathrm{fix}_{\mathbf{A}}(f)) = \mathrm{fix}_{\mathbf{B}}(g)$, *whenever* $f : \mathbf{A} \to \mathbf{A}$, $g : \mathbf{B} \to \mathbf{B}$, $h : \mathbf{A} \to \mathbf{B}$, *provided that* $h \circ f = g \circ h$ *and* $h(\bot_{\mathbf{A}}) = \bot_{\mathbf{B}}$. ■

Remarks on the space of strict mappings. In 7.4 and many other places we have had occasion to make use of mappings that take the bottom element of one domain over to the bottom element of the other domain. Such mappings are called *strict mappings* because they take a strict view of having empty input. As notation we might write

$$f : \mathbf{A} \to_{\blacksquare} \mathbf{B}$$

to mean that f is a strict approximable mapping (i.e. $f(\bot_{\mathbf{A}}) = \bot_{\mathbf{B}}$). The totality of domains and strict mappings forms an interesting category in itself, but it is best used in connection with the full category of all approximable mappings.

The collection of strict mappings forms a domain, too. The way to see this is to refer back to Definition 7.1 and add an additional clause ruling out non-strict mappings as inconsistent. What has to be added to 7.1(iii) is the conjunct on the right-hand side to the effect that if the condition $\emptyset \vdash_{\mathbf{A}} \bigcup\{u_i \mid i \in I\}$ holds, then $\emptyset \vdash_{\mathbf{B}} \bigcup\{v_i \mid i \in I\}$ holds too. By the same arguments we used before, it follows that this is the appropriate system for the domain of strict mappings. We can denote it by $(\mathbf{A} \to_{\blacksquare} \mathbf{B})$.

There is also a useful operator

$$\mathrm{strict} : (\mathbf{A} \to \mathbf{B}) \to (\mathbf{A} \to_{\blacksquare} \mathbf{B})$$

defined by the condition that for $f : \mathbf{A} \to \mathbf{B}$ we have:

$$u \; \mathit{strict}(f) \; v \text{ iff either } \emptyset \vdash_{\mathbf{B}} v \text{ or } \emptyset \nvdash_{\mathbf{A}} u \text{ and } u f v,$$

for all $u \in \mathrm{Con}_{\mathbf{A}}$ and $v \in \mathrm{Con}_{\mathbf{B}}$. This operator converts every approximable mapping into the largest strict mapping contained within it.

Since every strict mapping is an approximable mapping, there is also an obvious operator going the other way. The pair of operators shows that $\mathbf{A} \to_s \mathbf{B}$ as a domain is what is called a *retract* of $\mathbf{A} \to \mathbf{B}$. There is an interesting theory of this kind of relationship between domains, but we cannot enter into it here.

As a very small application of the use of strict mappings, we remark that the following two domains are isomorphic:

$$\mathbf{A} \times \mathbf{A} \cong (\mathbf{BOOL} \to_s \mathbf{A}).$$

The mapping from right to left is called the *conditional operator*, cond, and we have for all elements $x, y \in |\mathbf{A}|$ and $t \in |\mathbf{BOOL}|$

$$\mathrm{cond}(x, y)(t) = \begin{cases} x, & \text{if } t = \text{true}, \\ y, & \text{if } t = \text{false}. \end{cases} \blacksquare$$

Theorem (`proposition_7_4.ii`). The least fixed point of f is a fixed point: $f(\mathrm{fix}(f)) = \mathrm{fix}(f)$.

Proof. The fixed-point equality for the constructed fix element. ?

Theorem (`proposition_7_4.unique`). Any fixed point that is least among pre-fixed points equals the constructed fix element.

Proof. Leastness gives one inequality; the constructed fix element is itself a pre-fixed point. ?

Theorem (`proposition_7_4.iii`). Strict maps that intertwine endomaps preserve least fixed points.

Proof. Combine the two inequalities between the image of $\mathrm{fix}(f)$ and $\mathrm{fix}(g)$. ?

Theorem (`proposition_7_4`). The least fixed-point operator is uniquely determined by being an operator $\mathrm{fix}_{\mathbf{A}} : (\mathbf{A} \to \mathbf{A}) \to \mathbf{A}$ with $f(\mathrm{fix}(f)) = \mathrm{fix}(f)$ and preservation of least fixed points under strict intertwining maps.

Proof. Assemble the fixed-point equation, the intertwining property, and uniqueness among least pre-fixed points. ?

Theorem (`closure_empty_eq_bot`). The closure of the empty set is the bottom element.

Proof. Antisymmetry of the element order using empty entailment and the bottom axioms. ?

Theorem (`idMap_botElement`). The identity approximable map sends bottom to bottom.

Proof. Bottom is related only to data entailed by empty, hence lies in the bottom element. ?

Theorem (`fixChain_toElement_le_fix`). Along a fix-chain for f, the image under a strict map commuting with f and g stays below the fix element of g.

Proof. Induction on the chain, using the commuting square and strictness at bottom. ?

Theorem (`toElement_comp_fix_le`). Under a commuting square of maps with a strict mediator, the mediator sends fix-chains for f below fix of g.

Proof. Reduce to the chain lemma for the mediator applied along fix-chains. ?

Theorem (`fixElement_le_toElement_fix`). A strict map commuting with f and g sends $\mathrm{fix}(f)$ below $\mathrm{fix}(g)$.

Proof. Every token of $\mathrm{fix}(f)$ arises from a fix-chain; apply the chain comparison. ?

Theorem (`toElement_fix_le_fixElement`). A strict map commuting with f and g sends $\mathrm{fix}(f)$ above nothing beyond $\mathrm{fix}(g)$: the reverse inequality.

Proof. Use leastness of $\mathrm{fix}(g)$ among pre-fixed points after transporting the fixed-point property. ?

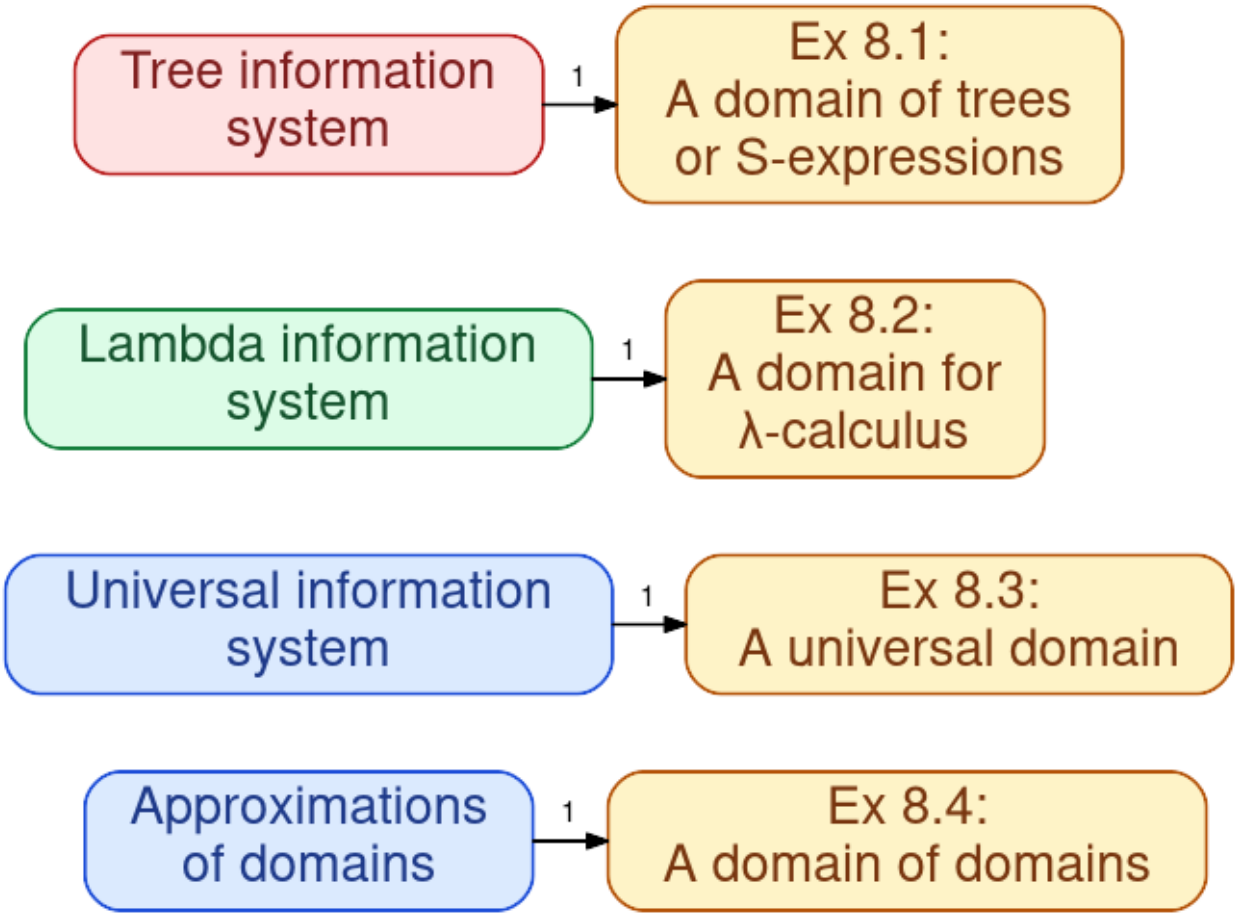

Figure 62: Diagram 27

5.9.1 Introduction

Having outlined the theory of several domain constructs, the final topic for this paper will be the discussion of the *iteration* of these constructs in giving *recursive*, rather than direct definitions of domains. These recursively defined systems have often been called "reflexive," because the domains generally contain copies of themselves as a part of their very structure. The way that this self-containment takes place is best expressed by the so-called *domain equations*, which are really isomorphisms that relate the domain as a whole to a combination of domains—usually with the main domain as a component. This description is rough, since recursion equations for domains can be as complex as recursion equations for functions. We will not enter into a full theory of domain equations now but will just review some preliminary examples to illustrate how the new presentation makes the constructions more explicit.

5.9.2 Tree information system

Definition (`pairLInsert` commutative). Insertion of left children commutes.

Proof. By cases on the two tokens, using commutativity of finite-set insertion. ?

Definition (`pairRInsert` commutative). Insertion of right children commutes.

Proof. By cases on the two tokens, using commutativity of finite-set insertion. ?

Definition (`atomInsert` commutative). Insertion of atoms commutes.

Proof. By cases on the two tokens, using commutativity of finite-set insertion. ?

Definition (`TreeToken`). A tree token is bottom, an atom from the given domain, or a left or right child of a tree token.

Definition (`instDecidableEqTreeToken`). There is a type-class instance for decidable equality Tree Token.

Definition (`atomInsert`). The atom insertion adds the payload of the matching constructor and leaves every other constructor unchanged.

Definition (`pairLInsert`). The left-child insertion adds the payload of the matching constructor and leaves every other constructor unchanged.

Definition (`pairLFinset`). The set of left children.

Theorem (`mem_foldr_pairL`). A token lies in the fold of left children exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_pairLFinset`). A token lies in the mem set of left children exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`pairRInsert`). The right-child insertion adds the payload of the matching constructor and leaves every other constructor unchanged.

Definition (`pairRFinset`). The set of right children.

Theorem (`mem_foldr_pairR`). A token lies in the fold of right children exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_pairRFinset`). A token lies in the mem set of right children exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`atomFinset`). The atom finite set.

Definition (`TreeCon`). A finite set of tree tokens is consistent when every finite selection of atoms is consistent in **A** and the left and right children are themselves consistent.

Theorem (`TreeCon.atom_con_of_atoms`). The statement atom con of atoms holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon.atoms_empty_of_right`). The atoms empty of right of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon.pairs_empty_of_left`). The pairs empty of left of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_empty`). The atom finite set empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`eq_singleton_bot_of_subset`). The property eq singleton bot of subset passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_foldr_atom`). A token lies in the mem foldr atom exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_empty`). The set of left children empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_insert_atom`). Inserting the indicated constructor updates set of left children insert atom by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_insert_bot`). Inserting the indicated constructor updates set of left children insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_insert_pairL`). Inserting the indicated constructor updates set of left children insert pair L by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_insert_pairR`). Inserting the indicated constructor updates set of left children insert pair R by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_mono`). The operation set of left children mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_singleton_atom`). On a singleton, set of left children singleton atom returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_singleton_bot`). On a singleton, set of left children singleton bot returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_singleton_pairL`). On a singleton, set of left children singleton pair L returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairLFinset_singleton_pairR`). On a singleton, set of left children singleton pair R returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_empty`). The set of right children empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_insert_atom`). Inserting the indicated constructor updates set of right children insert atom by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_insert_bot`). Inserting the indicated constructor updates set of right children insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_insert_pairL`). Inserting the indicated constructor updates set of right children insert pair L by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_insert_pairR`). Inserting the indicated constructor updates set of right children insert pair R by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_mono`). The operation set of right children mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_singleton_atom`). On a singleton, set of right children singleton atom returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_singleton_bot`). On a singleton, set of right children singleton bot returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_singleton_pairL`). On a singleton, set of right children singleton pair L returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairRFinset_singleton_pairR`). On a singleton, set of right children singleton pair R returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`treeBot`). The bottom tree token is the least informative token.

Theorem (`mem_atomFinset`). A token lies in the mem atom finite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon_empty`). The tree Con empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_insert_atom`). Inserting the indicated constructor updates atom finite set insert atom by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_insert_bot`). Inserting the indicated constructor updates atom finite set insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_insert_pairL`). Inserting the indicated constructor updates atom finite set insert pair L by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_insert_pairR`). Inserting the indicated constructor updates atom finite set insert pair R by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_mono`). The operation atom finite set mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_singleton_atom`). On a singleton, atom finite set singleton atom returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_singleton_bot`). On a singleton, atom finite set singleton bot returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_singleton_pairL`). On a singleton, atom finite set singleton pair L returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`atomFinset_singleton_pairR`). On a singleton, atom finite set singleton pair R returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon.pairL_of_right`). The statement pair L of right holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon.pairR_of_right`). The statement pair R of right holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon_insert_bot`). Inserting the indicated constructor updates tree Con insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon_subset`). The property tree Con subset passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon_singleton`). On a singleton, tree Con singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`TreeEntPayload`). The tree Ent Payload.

Theorem (`TreeEntPayload.of_mem`). The statement of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeEntPayload.of_no_atoms_no_pairs`). The statement of no atoms no pairs holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`TreeEnt`). Tree entailment is the entailment of the tree domain.

Theorem (`TreeEnt.of_mem`). The statement of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeCon_insert_of_ent`). Inserting the indicated constructor updates tree Con insert of ent by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairL_ne_or_subset_bot`). The property pair L ne or subset bot passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`pairR_ne_or_subset_bot`). The property pair R ne or subset bot passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeEntPayload_trans`). The relation tree Ent Payload trans is transitive.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`TreeEnt_trans`). The relation tree Ent trans is transitive.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`treeSystem`). The tree domain over $\mathbf{A}$ is the information system whose tokens are tree tokens, whose consistency is tree consistency, and whose entailment is tree entailment.

Definition (`treeRhs`). The right-hand side of the tree equation is the sum of $\mathbf{A}$ with the product of the tree domain with itself.

Theorem (`treeRhs.eq_sum_product`). The equality eq sum product holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`treeUnfold`). Unfolding a tree token views it as a token of $\mathbf{A} + (\mathbf{T} \times \mathbf{T})$.

Theorem (`treeUnfold.atom`). The statement atom holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`treeUnfold.bot`). The statement bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`treeUnfold.pairL`). The statement pair L holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`treeUnfold.pairR`). The statement pair R holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`treeUnfold.pairL_bot_eq_pairR_bot`). The equality pair L bot eq pair R bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

5.9.3 Example 8.1: A domain of trees or S-expressions

A domain of trees or S-expressions. This is everyone's favorite example. And a very nice example it is, but we should not think that it contains all the meat of the theory of domain equations. Even if we generalize the kinds of equations to contain all iterations of the domain constructs $+$ and $\times$, the full power of the method has not been exploited. We will try to make this clear in the further examples.

Let a domain (information system) $\mathbf{A}$ be given. What we want to construct is a domain $\mathbf{T}$ of "trees" built up from elements of $\mathbf{A}$ as "atoms". For simplicity we consider unlabelled binary trees here, but more complex trees are easy to accommodate. The domain equation we want to "solve" is this one:

$$\mathbf{T} \cong \mathbf{A} + (\mathbf{T} \times \mathbf{T}).$$

If such a domain exists, then we can say that (up to isomorphism) the elements of the domain $\mathbf{T}$ are either bottom, or elements of the given domain $\mathbf{A}$, or pairs of elements from the domain $\mathbf{T}$ itself. And these are the only kinds of elements that $\mathbf{T}$ has.

To prove that such a domain exists it is only necessary to ask what information has to be given about a prospective element. The answer may involve us in a regress, but the running backwards need not be infinite—at least for the finite elements. As we shall see, the infinite elements of $\mathbf{T}$ can be self-replicating; but, to define a domain fully, all we have to do is to build up the finite elements out of the data objects in a systematic way. Fortunately, in order to satisfy the above equation, the required closure conditions on data objects are simple to achieve.

In the first place, we need copies of all the data objects of $\mathbf{A}$ to put into the sum. The easy way to do this is to take an object Δ not in $D_{\mathbf{A}}$, and to let, by definition,

$$\Delta_{\mathbf{T}} = (\Delta, \Delta).$$

That gives us one member of $D_{\mathbf{T}}$, the one we always have to have in any case. The copy of an $X \in D_{\mathbf{A}}$ is just going to be (X, Δ). The other members of $D_{\mathbf{T}}$ will be of the form (Δ, U), where U gives us information about the other kind of elements of $\mathbf{T}$. The point is that $\mathbf{T}$ has to be a sum, and we are using just the scheme of Definition 6.3 to set this up.

Next we have to think what kind of information the U above should contain. Because we want a product, we refer back to Definition 6.1 and imagine we have already defined $D_{\mathbf{T}}$. What 6.1(i) suggests is that we throw in a bunch of other data objects into $D_{\mathbf{T}}$. The only point that needs care is that the data objects for the product must be copied into the overall sum. With this in mind, the following clauses give us the inductive definition of $D_{\mathbf{T}}$:

(1) $\Delta_{\mathbf{T}} \in D_{\mathbf{T}}$;

(2) $(X, \Delta) \in D_{\mathbf{T}}$ whenever $X \in D_{\mathbf{A}}$; and

(3) $(\Delta, (Y, \Delta_{\mathbf{T}})) \in D_{\mathbf{T}}$, and $(\Delta, (\Delta_{\mathbf{T}}, Z)) \in D_{\mathbf{T}}$ whenever $Y, Z \in D_{\mathbf{T}}$.

Of course, when we say "inductive definition," we mean that $D_{\mathbf{T}}$ is the least class satisfying (1)–(3). By standard arguments it can be shown that $D_{\mathbf{T}}$ satisfies this set-theoretical equation:

$$D_{\mathbf{T}} = \{\Delta_{\mathbf{T}}\} \cup \{(X, \Delta) \mid X \in D_{\mathbf{A}}\} \cup \{(\Delta, (Y, \Delta_{\mathbf{T}})) \mid Y \in D_{\mathbf{T}}\} \cup \{(\Delta, (\Delta_{\mathbf{T}}, Z)) \mid Z \in D_{\mathbf{T}}\}.$$

In fact, with some very mild assumptions about ordered pairs in set theory, $D_{\mathbf{T}}$ is the only solution to the above equation.

Defining the data objects is but part of the story: the same data objects can enter into quite different information systems. Data objects are just "tokens" and are only given "meaning" when $\mathrm{Con}_{\mathbf{T}}$ and $\vdash_{\mathbf{T}}$ are defined. Let us consider the problem of consistency first. We already understand the notion as it applies to sum and product systems, so we must merely copy over the parts of the previous definitions in the right position for the definition of $\mathrm{Con}_{\mathbf{T}}$. There are two forms we could give this definition; perhaps the best is the inductive one. We have:

(4) $\emptyset \in \mathrm{Con}_{\mathbf{T}}$;

(5) $u \cup \{\Delta_{\mathbf{T}}\} \in \mathrm{Con}_{\mathbf{T}}$ whenever $u \in \mathrm{Con}_{\mathbf{T}}$;

(6) $\{(X, \Delta) \mid X \in w\} \in \mathrm{Con}_{\mathbf{T}}$ whenever $w \in \mathrm{Con}_{\mathbf{A}}$;

(7) $\{(\Delta, (Y, \Delta_{\mathbf{T}})) \mid Y \in u\} \cup \{(\Delta, (\Delta_{\mathbf{T}}, Z)) \mid Z \in v\} \in \mathrm{Con}_{\mathbf{T}}$ whenever $u, v \in \mathrm{Con}_{\mathbf{T}}$.

Conditions (4)–(7) certainly make the inductive character of $\mathrm{Con}_{\mathbf{T}}$ clear—again, let us emphasize, the set being specified is the least such. Also clear from the definition is the fact that a consistent set of $\mathbf{T}$—aside from containing $\Delta_{\mathbf{T}}$—is either a copy of a consistent set of $\mathbf{A}$ or a copy of a consistent set of $\mathbf{T} \times \mathbf{T}$. We could thus state a set-theoretical equation for $\mathrm{Con}_{\mathbf{T}}$ similar to the one for $D_{\mathbf{T}}$.

It remains to define entailment for $\mathbf{T}$. Here are the inductive clauses which are pretty much forced on us by our objective of solving the domain equation:

(8) $u \vdash_{\mathbf{T}} \Delta_{\mathbf{T}}$ always;

(9) $u \cup \{\Delta_{\mathbf{T}}\} \vdash_{\mathbf{T}} Y$ whenever $u \vdash_{\mathbf{T}} Y$;

(10) $\{(X, \Delta) \mid X \in w\} \vdash_{\mathbf{T}} (W, \Delta)$ whenever $w \vdash_{\mathbf{A}} W$;

(11) $\{(\Delta, (Y, \Delta_{\mathbf{T}})) \mid Y \in u\} \cup \{(\Delta, (\Delta_{\mathbf{T}}, Z)) \mid Z \in v\} \vdash_{\mathbf{T}} (\Delta, (X, \Delta_{\mathbf{T}}))$ whenever $u \vdash_{\mathbf{T}} X$ and $v \in \mathrm{Con}_{\mathbf{T}}$; and

(12) $\{(\Delta, (Y, \Delta_{\mathbf{T}})) \mid Y \in u\} \cup \{(\Delta, (\Delta_{\mathbf{T}}, Z)) \mid Z \in v\} \vdash_{\mathbf{T}} (\Delta, (\Delta_{\mathbf{T}}, X))$ whenever $v \vdash_{\mathbf{T}} X$ and $u \in \mathrm{Con}_{\mathbf{T}}$.

Inductive definitions engender inductive proofs. It now has to be checked that consistency and entailment for $\mathbf{T}$ satisfy the axioms of 2.1. The steps needed for this check are mechanical. (The proof may be aided by noting that the cases in (4)–(7) and in (8)–(12) are disjoint—except for a trivial overlap between (8) and (9). The cases get invoked typically by asking, when confronted with an entailment to prove, for the nature of the data object on the right of the turnstile.)

Having defined and verified that $\mathbf{T}$ is an information system, the validity of the domain equation for $\mathbf{T}$ is secured by forming the right-hand side and noting that $\mathbf{T}$ is *identical* to $\mathbf{A} + (\mathbf{T} \times \mathbf{T})$. The reason is that we carefully chose the notation to match the official definitions of sums and products. (In general, in solving domain equations some transformation might have to take place to "re-format" data objects if things are not set up to be literally the same.)

It should be remarked that the sense can be made precise in which $\mathbf{T}$ is the *least* solution of the given domain equation. (It is an initial algebra in a suitable category of algebras and algebra homomorphisms.) It is pretty obvious that it is minimal in some sense, because we put into it only what was strictly required by the problem and nothing more.

It is also fairly obvious that there are *many* solutions to this domain equation. A non-constructive way to obtain non-minimal solutions is to interpret the whole construction of $\mathbf{T}$ in a non-standard model of set theory. Though, in the definition of $D_{\mathbf{T}}$, it looks like we are only working with very finite objects, everything we did could be made abstract and could be carried out in some funny universe. The result would be a system of "finite" data objects having all the right formal properties but containing things not in the standard minimal system. We would then take the notions of consistency and entailment that also exist in the funny universe and

restrict them to sets of data objects that are actually finite in the standard sense. It can be seen from the formal properties of the construction that the resulting notions satisfy our axioms for an information system

and that the domain equation holds—BUT the system would have many different elements beyond what we put into the original $\mathbf{T}$. To make this construction work, by the way, we would have to force $\mathbf{A}$ to be absolute in the model: if it is actually finite (say, $\mathbf{A} = \mathbf{BOOL}$), then there is no problem. (Constructive methods for introducing "nonstandard" data objects can also be given.)

Finally, we must remark on why we called $\mathbf{T}$ a domain of S-expressions. The answer becomes clear when we structure $\mathbf{T}$ as an algebra. First, there is an approximable mapping

$$\text{atom} : \mathbf{A} \to \mathbf{T},$$

which injects $\mathbf{A}$ into $\mathbf{T}$ making the elements of $\mathbf{A}$ "atoms" of $\mathbf{T}$. Then there is a truth-valued predicate on $\mathbf{T}$ which decides whether an element is an atom:

$$\text{isatom} : \mathbf{T} \to \mathbf{BOOL}.$$

Finally, since $\mathbf{T} \times \mathbf{T}$ is a part of $\mathbf{T}$, we can redefine the paring functions so that:

$$\text{pair} : \mathbf{T} \times \mathbf{T} \to \mathbf{T}, \quad \text{fst} : \mathbf{T} \to \mathbf{T}, \quad \text{and snd} : \mathbf{T} \to \mathbf{T}.$$

In LISP terminology, these operations are the same as the familiar cons, car, and cdr. This makes $\mathbf{T}$ into an algebra where, starting from atoms, elements—expressions—can be built up by iterated pairing.

But why is our system different from the usual way of regarding S-expressions? The answer is that by including partial expressions (those involving $\Delta_{\mathbf{T}}$) and by completing the domain with limits, *infinite* expressions are introduced. For instance, if $a \in |\mathbf{T}|$, then we can solve the fixed-point equation:

$$x = \text{pair}(\text{atom}(a), x),$$

which is an infinite list of a's. This is but one example; the possibilities have been discussed in many papers too numerous to mention here.

As is common to remark, S-expressions can also be thought of as trees: the parse tree that gives the grammatical form of the expression. What we have added to the idea of a tree is the possibility of having infinite trees, and having all these trees as elements of a domain. ■

Theorem (`example_8_1`). The right-hand side of the tree equation is the sum of the given domain with the product of the tree domain with itself: $\mathbf{T}$ and $\mathbf{A} + (\mathbf{T} \times \mathbf{T})$ have the same information system of tokens.

Proof. The right-hand side is defined to be that sum, so the two systems agree. ?

5.9.4 Lambda information system

Definition (`RawLamToken` equality). Equality of raw lambda tokens is decidable, by the boolean equality on those tokens.

Definition (`lamAtomInsert` commutative). Insertion of lambda atoms commutes.

Proof. By cases on the two tokens and commutativity of finite-set insertion. ?

Definition (`lamFunInsert` commutative). Insertion of function tokens commutes.

Proof. By cases on the two tokens and commutativity of finite-set insertion. ?

Definition (`maxDepthInsert` commutative). The binary maximum on depths commutes in its first arguments.

Proof. By commutativity of the maximum of natural numbers. ?

Definition (`LamToken` equality). Equality of lambda tokens is decidable.

Proof. It is equality of the underlying raw tokens. ?

Definition (`lamForgetInsert` commutative). Forgetful insertion commutes.

Proof. By cases on the two tokens and commutativity of finite-set insertion. ?

Definition (`LamDToken` equality). Equality of depth-bounded lambda tokens is decidable.

Proof. It is equality of the underlying tokens. ?

Definition (`lamDForgetInsert` commutative). Depth-bounded forgetful insertion commutes.

Proof. By cases on the two tokens and commutativity of finite-set insertion. ?

Definition (`RawLamToken`). A raw lambda token is bottom, an atom, or a function token pairing a list of input tokens with a list of output tokens.

Definition (`rawLamBEq`). The raw lambda boolean equality.

Definition (`rawLamListBEq`). The raw lambda List boolean equality.

Theorem (`rawLamBEq_eq`). The equality raw lambda boolean equality eq holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`rawLamListBEq_eq`). The equality raw lambda List boolean equality eq holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`lamAtomInsert`). The lambda Atom Insert adds the payload of the matching constructor and leaves every other constructor unchanged.

Definition (`lamFunInsert`). The lambda function Insert adds the payload of the matching constructor and leaves every other constructor unchanged.

Definition (`listToFinset`). The list To finite set.

Definition (`lamAtomFinset`). The lambda Atom finite set.

Definition (`lamFunFinset`). The lambda function finite set.

Definition (`lamInUnionInsert`). The lambda In Union Insert adds the payload of the matching constructor and leaves every other constructor unchanged.

Definition (`lamOutUnionInsert`). The lambda Out Union Insert adds the payload of the matching constructor and leaves every other constructor unchanged.

Theorem (`mem_listToFinset`). A token lies in the mem list To finite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_lamFunFinset`). A token lies in the mem lambda function finite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`[DecidableEq`). There is a type-class instance for [Decidable Eq.

Definition (`lamInputUnion`). The lambda Input Union.

Definition (`lamOutputUnion`). The lambda Output Union.

Theorem (`max_le_max_nat`). The statement max le max nat holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`rawDepth`). The raw Depth.

Theorem (`mem_lamInputUnion`). A token lies in the mem lambda Input Union exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_lamOutputUnion`). A token lies in the mem lambda Output Union exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`foldl_max_ge_init`). The statement foldl max ge init holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`foldl_max_mono_init`). The operation foldl max mono init preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`maxDepthInsert`). The max Depth Insert adds the payload of the matching constructor and leaves every other constructor unchanged.

Theorem (`foldl_list_le_of_mem`). The statement foldl list le of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`rawDepth_funTok_gt_left`). The statement raw Depth fun Tok gt left holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`rawDepth_funTok_gt_right`). The statement raw Depth fun Tok gt right holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`foldr_max_le_of_forall`). The statement foldr max le of forall holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`foldr_max_lt_of_forall`). The statement foldr max lt of forall holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`finsetMaxDepth`). The finset Max Depth.

Theorem (`finsetMaxDepth.listToFinset_le`). The statement list To finite set le holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`finsetMaxDepth.list_lt_funTok`). The statement list lt fun Tok holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`le_finsetMaxDepth_of_mem`). The statement le finset Max Depth of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`finsetMaxDepth.inputUnion_lt`). The operation input Union lt preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`finsetMaxDepth.outputUnion_lt`). The operation output Union lt preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`finsetMaxDepth.list_lt_funTok_out`). The statement list lt fun Tok out holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`finsetMaxDepth.of_mem_funTok`). The statement of mem fun Tok holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`LamConDepth`). The lambda Con Depth.

Definition (`LamEntDepth`). The lambda Ent Depth are given by the listed constructors.

Theorem (`LamEntDepth_bot`). The statement lambda Ent Depth bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEntDepth.con`). The statement con holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`LamConN`). The lambda Con N.

Theorem (`lamAtomFinset_empty`). The lambda Atom finite set empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamFunFinset_empty`). The lambda function finite set empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamFunFinset_insert_atom`). Inserting the indicated constructor updates lambda function finite set insert atom by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamFunFinset_insert_bot`). Inserting the indicated constructor updates lambda function finite set insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamFunFinset_insert_funTok`). Inserting the indicated constructor updates lambda function finite set insert fun Tok by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamFunFinset_mono`). The operation lambda function finite set mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamInputUnion_empty`). The lambda Input Union empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamOutputUnion_empty`). The lambda Output Union empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_lamAtomFinset`). A token lies in the mem lambda Atom finite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`LamCon`). The lambda Con.

Theorem (`lamAtomFinset_insert_atom`). Inserting the indicated constructor updates lambda Atom finite set insert atom by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamAtomFinset_insert_bot`). Inserting the indicated constructor updates lambda Atom finite set insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamAtomFinset_insert_funTok`). Inserting the indicated constructor updates lambda Atom finite set insert fun Tok by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamAtomFinset_mono`). The operation lambda Atom finite set mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`IsLamToken`). The is lambda Token are given by the listed constructors.

Definition (`LamToken`). The lambda Token.

Definition (`lamBot`). The lambda Bot.

Definition (`lamForget`). The lambda Forget.

Definition (`lamForgetInsert`). The lambda Forget Insert adds the payload of the matching constructor and leaves every other constructor unchanged.

Theorem (`LamConDepth_empty`). The lambda Con Depth empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConDepth_of_fun_empty`). The lambda Con Depth of fun empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConDepth_of_fun_nonempty`). The lambda Con Depth of fun nonempty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEntDepth_weaken_fun`). The statement lambda Ent Depth weaken fun holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`LamEntN`). The lambda Ent N.

Definition (`LamWF`). The lambda WF are given by the listed constructors.

Theorem (`filter_ne_subset_of_subset_insert_lam`). The property filter ne subset of subset insert lambda passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`finsetMaxDepth_funion_le`). The operation finset Max Depth union le preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`finsetMaxDepth_insert_le`). Inserting the indicated constructor updates finset Max Depth insert le by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`funion_assoc_lam`). The operation union assoc lambda preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`funion_comm_lam`). The operation union comm lambda preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`funion_empty_right_lam`). The union empty right lambda of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`insert_filter_ne_lam`). Inserting the indicated constructor updates insert filter ne lambda by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamAtomFinset_singleton_funTok`). On a singleton, lambda Atom finite set singleton fun Tok returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`lamForgetFinset`). The lambda Forget finite set.

Theorem (`lamFunFinset_funion`). The operation lambda function finite set union preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamFunFinset_singleton_funTok`). On a singleton, lambda function finite set singleton fun Tok returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamInputUnion_funion`). The operation lambda Input Union union preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamInputUnion_insert`). Inserting the indicated constructor updates lambda Input Union insert by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamInputUnion_singleton`). On a singleton, lambda Input Union singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamOutputUnion_funion`). The operation lambda Output Union union preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamOutputUnion_insert`). Inserting the indicated constructor updates lambda Output Union insert by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamOutputUnion_singleton`). On a singleton, lambda Output Union singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConDepth_insert_atom`). Inserting the indicated constructor updates lambda Con Depth insert atom by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConDepth_singleton_atom`). On a singleton, lambda Con Depth singleton atom returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConDepth_singleton_bot`). On a singleton, lambda Con Depth singleton bot returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEntDepth_weaken_atom`). The statement lambda Ent Depth weaken atom holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConDepth_insert_bot`). Inserting the indicated constructor updates lambda Con Depth insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConDepth_mono`). The operation lambda Con Depth mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`LamEnt`). The lambda Ent.

Definition (`LamDToken`). The lambda DToken.

Definition (`LamTokenCon`). The lambda Token Con.

Theorem (`LamEntDepth_of_mem`). The statement lambda Ent Depth of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEntDepth_weaken_insert`). Inserting the indicated constructor updates lambda Ent Depth weaken insert by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`LamTokenEnt`). The lambda Token Ent.

Theorem (`LamConDepth_funion_of_entSet`). The operation lambda Con Depth union of ent Set preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`lamDBot`). The lambda DBot.

Definition (`lamDForget`). The lambda DForget.

Theorem (`LamConDepth_insert_of_ent`). Inserting the indicated constructor updates lambda Con Depth insert of ent by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`lamDForgetInsert`). The lambda DForget Insert adds the payload of the matching constructor and leaves every other constructor unchanged.

Theorem (`LamEntDepth_trans`). The relation lambda Ent Depth trans is transitive.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`IsLamWF_of_mem`). The statement is lambda WF of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConDepth_singleton_funTok`). On a singleton, lambda Con Depth singleton fun Tok returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`listToLamDFinset`). The list To lambda Dfinite set.

Theorem (`mem_foldr_lamDForget`). A token lies in the mem foldr lambda DForget exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_listToLamDFinset`). A token lies in the mem list To lambda Dfinite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`lamDForgetFinset`). The lambda DForget finite set.

Theorem (`mem_lamDForgetFinset`). A token lies in the mem lambda DForget finite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamDForgetFinset.insert`). Inserting the indicated constructor updates insert by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamDForgetFinset.mono`). The operation mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamDForgetFinset.singleton`). On a singleton, singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamDForget_listToLamDFinset`). The statement lambda DForget list To lambda Dfinite set holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`LamDCon`). The lambda DCon.

Theorem (`LamDCon.singleton`). On a singleton, singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamDCon.listToLamDFinset`). The statement list To lambda Dfinite set holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamDCon.subset`). The property subset passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`LamDEnt`). The lambda DEnt.

Theorem (`LamDEnt.bot`). The statement bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamDEnt.of_mem`). The statement of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamDEnt.trans`). The relation trans is transitive.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamDCon_insert_of_ent`). Inserting the indicated constructor updates lambda DCon insert of ent by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`lambdaSystem`). The lambda domain over $\mathbf{A}$ is the information system of well-formed lambda tokens, with lambda consistency and lambda entailment.

Definition (`lamRhs`). The right-hand side of the lambda equation is the sum of $\mathbf{A}$ with the function space of the lambda domain with itself.

Definition (`lamUnfold`). Unfolding a lambda token views it as a token of $\mathbf{A} + (\mathbf{D} \to \mathbf{D})$.

Theorem (`mem_foldr_lamForget`). A token lies in the mem foldr lambda Forget exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`funion_insert_lam`). Inserting the indicated constructor updates union insert lambda by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_atom_con`). The statement lambda Con N atom con holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_atom_empty`). The lambda Con N atom empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_down_atom`). The statement lambda Con N down atom holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_empty`). The lambda Con N empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_exists_FunCon`). The statement lambda Con N exists function Con holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_fun_FunCon_right`). The statement lambda Con N fun function Con right holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_fun_empty`). The lambda Con N fun empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_insert_bot`). Inserting the indicated constructor updates lambda Con N insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_mono`). The operation lambda Con N mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamCon_empty`). The lambda Con empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamCon_singleton_atom`). On a singleton, lambda Con singleton atom returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamCon_singleton_bot`). On a singleton, lambda Con singleton bot returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamCon_subset`). The property lambda Con subset passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEntN_con`). The statement lambda Ent N con holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEntN_mono`). The operation lambda Ent N mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEnt_bot`). The statement lambda Ent bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamAtomFinset_funion`). The operation lambda Atom finite set union preserves union.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamDForgetFinset_empty`). The lambda DForget finite set empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamForgetFinset_empty`). The lambda Forget finite set empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamRhs_eq_sum_function`). The equality lambda Rhs eq sum function holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamUnfold_atom`). The statement lambda Unfold atom holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamUnfold_bot`). The statement lambda Unfold bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_lamForgetFinset`). A token lies in the mem lambda Forget finite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_FunCon_mono_atom`). The operation lambda Con N function Con mono atom preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_fun_wf`). The statement lambda Con N fun wf holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_insert_of_ent_atom`). Inserting the indicated constructor updates lambda Con N insert of ent atom by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamCon_singleton_funTok`). On a singleton, lambda Con singleton fun Tok returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_insert_of_ent_bot`). Inserting the indicated constructor updates lambda Con N insert of ent bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEnt_con`). The statement lambda Ent con holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamTokenEnt_bot`). The statement lambda Token Ent bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamDCon_empty`). The lambda DCon empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamTokenCon_empty`). The lambda Token Con empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamTokenCon_subset`). The property lambda Token Con subset passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamForgetFinset_insert`). Inserting the indicated constructor updates lambda Forget finite set insert by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lamForgetFinset_singleton`). On a singleton, lambda Forget finite set singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamConN_fun_FunCon_atom`). The statement lambda Con N fun function Con atom holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEntN_of_mem`). The statement lambda Ent N of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamCon_of_forget_singleton`). On a singleton, lambda Con of forget singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamEnt_of_mem`). The statement lambda Ent of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamTokenCon_singleton`). On a singleton, lambda Token Con singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`LamTokenEnt_of_mem`). The statement lambda Token Ent of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`lambdaSystem_con_axioms`). The statement lambdabda System con axioms holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

5.9.5 Example 8.2: A domain for λ-calculus

A domain for λ-claculus. A lengthy discussion with many references on λ-calculus models can be found in [**?**]. All we wish to remark on here is how the method of construction by solving a domain equation can be fit into the new presentation. What I have added to the previous ideas (that in any case came out of an analysis of finite elements of models) is the general view of information systems. In particular the models obtained this way are *not* lattices—hence, the need for the calculations with Con. I hope that the presentation here makes it clearer how "pure" λ-calculus models can be related to other domains having other types of structures—for instance, those needed in denotational semantics.

The domain equation we wish to solve is:

$$\mathbf{D} \cong \mathbf{A} + (\mathbf{D} \to \mathbf{D}).$$

We proceed in much the same way we did for $\mathbf{T}$, except we must now put in data objects appropriate to the function space. Here is construction, where again Δ is chosen outside $D_{\mathbf{A}}$ and $\Delta_{\mathbf{D}} = (\Delta, \Delta)$:

(1) $\Delta_{\mathbf{D}} \in D_{\mathbf{D}}$;

(2) $(X, \Delta) \in D_{\mathbf{D}}$ whenever $X \in D_{\mathbf{A}}$;

(3) $(\Delta, (u, v)) \in D_{\mathbf{D}}$ whenever $u, v \in \mathrm{Con}_{\mathbf{D}}$;

(4) $\emptyset \in \mathrm{Con}_{\mathbf{D}}$;

(5) $u \cup \{\Delta_{\mathbf{D}}\} \in \mathrm{Con}_{\mathbf{D}}$ whenever $u \in \mathrm{Con}_{\mathbf{D}}$;

(6) $\{(X, \Delta) \mid X \in w\} \in \mathrm{Con}_{\mathbf{D}}$ whenever $w \in \mathrm{Con}_{\mathbf{A}}$; and

(7) $\{(\Delta, (u_0, v_0)), \ldots, (\Delta, (u_{n-1}, v_{n-1}))\} \in \mathrm{Con}_{\mathbf{D}}$ provided $u_i, v_i \in \mathrm{Con}_{\mathbf{D}}$ for all $i < n$ and whenever $I \subseteq \{0, \ldots, n-1\}$ and $\bigcup\{u_i \mid i \in I\} \in \mathrm{Con}_{\mathbf{D}}$, then $\bigcup\{v_i \mid i \in I\} \in \mathrm{Con}_{\mathbf{D}}$.

What is different here from the definition of $\mathbf{T}$ is the fact that the concepts $D_{\mathbf{D}}$ and $\mathrm{Con}_{\mathbf{D}}$ are mutually recursive because the data objects are themselves built from consistent sets. The scheme is based on a combination of the sum construct and the function-space construct, but the mutual recursion allows "feedback" to occur.

To complete the definition we have to give the clauses for the inductive definition of entailment. They are:

(8) $u \vdash_{\mathbf{D}} \Delta_{\mathbf{D}}$ always;

(9) $u \cup \{\Delta_{\mathbf{D}}\} \vdash_{\mathbf{D}} Y$ whenever $u \vdash_{\mathbf{D}} Y$;

(10) $\{(X, \Delta) \mid X \in w\} \vdash_{\mathbf{D}} (W, \Delta)$ whenever $w \vdash_{\mathbf{A}} W$;

(11) $\{(\Delta, (u_0, v_0)), \ldots, (\Delta, (u_{n-1}, v_{n-1}))\} \vdash_{\mathbf{D}} (\Delta, (u', v'))$ whenever $\bigcup\{v_i \mid u' \vdash_{\mathbf{D}} u_i\} \vdash_{\mathbf{D}} v'$ and the set on the left is in $\mathrm{Con}_{\mathbf{D}}$.

Obviously these definitions are much shorter if we have a domain in which all sets are consistent, but there are many reasons for retaining the consistency concept throughout. The check that $\mathbf{D}$ is an information system and satisfies the domain equation is mechanical. We cannot detail here how this construction provides a λ-calculus model.

It is clear that these definitions are constructive, and that, with a suitable Gödel numbering of the data objects, the predicates for consistency and entailment are recursively enumerable. However, the recursion used builds up the predicates by going from less complicated data objects to more complicated ones; therefore, the predicates must be recursive, because, for a certain size data object, the derivation that puts it into the predicate is of a bounded length. This observation helps in the discussion of the computability of the operators defined on these domains—another topic we cannot discuss here. ■

Theorem (`example_8_2`). The right-hand side of the λ-calculus equation is the sum of the given domain with the function space of the solution with itself: $\mathbf{D}$ and $\mathbf{A} + (\mathbf{D} \to \mathbf{D})$ have the same information system of tokens.

Proof. The right-hand side is defined to be that sum of a function space, so the two systems agree. ?

5.9.6 Universal information system

Definition (`pairLInsert` commutative). Insertion of left children in the topped domain commutes.

Proof. By cases on the two tokens and commutativity of finite-set insertion. ?

Definition (`pairRInsert` commutative). Insertion of right children in the topped domain commutes.

Proof. By cases on the two tokens and commutativity of finite-set insertion. ?

Definition (`IsUToken` decidable). Whether a topped token belongs to the universal domain is decidable.

Proof. By cases on the token, excluding the top. ?

Definition (`UToken` equality). Equality of universal tokens is decidable.

Proof. It is equality of the underlying topped tokens. ?

Definition (`uForgetInsert` commutative). Forgetting the top commutes with insertion.

Proof. By commutativity of finite-set insertion. ?

Definition (`VToken`). A token of the topped domain is bottom, top, or a left or right child.

Definition (`pairLInsert`). The left-child insertion adds the payload of the matching constructor and leaves every other constructor unchanged.

Definition (`vPairLFinset`). The v Pair Lfinite set.

Theorem (`mem_foldr_pairL`). A token lies in the fold of left children exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_vPairLFinset`). A token lies in the mem v Pair Lfinite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairLFinset.insert_top`). Inserting the indicated constructor updates insert top by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`pairRInsert`). The right-child insertion adds the payload of the matching constructor and leaves every other constructor unchanged.

Definition (`vPairRFinset`). The v Pair Rfinite set.

Theorem (`mem_foldr_pairR`). A token lies in the fold of right children exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_vPairRFinset`). A token lies in the mem v Pair Rfinite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairRFinset.empty`). The empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairRFinset.insert_top`). Inserting the indicated constructor updates insert top by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`VEnt`). The vEnt are given by the listed constructors.

Theorem (`VEnt.of_ent_top`). The statement of ent top holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`VEnt.of_mem`). The statement of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`VEnt.pairL_inv`). The statement pair L inv holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`VEnt.pairLFinset_of_EntSet`). The statement set of left children of Ent Set holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`VEnt.pairR_inv`). The statement pair R inv holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`VEnt.pairRFinset_of_EntSet`). The statement set of right children of Ent Set holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`VEnt.trans`). The relation trans is transitive.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`IsUToken`). The is UToken are given by the listed constructors.

Definition (`VCon`). The vCon.

Theorem (`VCon.any`). The statement any holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`vBot`). The v Bot.

Theorem (`vPairLFinset_empty`). The v Pair Lfinite set empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairLFinset_insert_bot`). Inserting the indicated constructor updates v Pair Lfinite set insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairLFinset_insert_pairL`). Inserting the indicated constructor updates v Pair Lfinite set insert pair L by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairLFinset_insert_pairR`). Inserting the indicated constructor updates v Pair Lfinite set insert pair R by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairLFinset_mono`). The operation v Pair Lfinite set mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairRFinset_insert_bot`). Inserting the indicated constructor updates v Pair Rfinite set insert bot by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairRFinset_insert_pairL`). Inserting the indicated constructor updates v Pair Rfinite set insert pair L by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairRFinset_insert_pairR`). Inserting the indicated constructor updates v Pair Rfinite set insert pair R by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vPairRFinset_mono`). The operation v Pair Rfinite set mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`vTop`). The v Top.

Definition (`vSystem`). The topped domain is the information system with a top element whose tokens are closed under pairing.

Theorem (`not_VEnt_empty_top`). The claim not VEnt empty top fails.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`VEnt_mono`). The operation vEnt mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`UToken`). A universal token is a token of the topped domain other than the top.

Definition (`vRhs`). The right-hand side of the recursion for the topped domain is the product of that domain with itself, plus bottom and top.

Theorem (`vRhs.eq_product`). The equality eq product holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`vUnfold`). Unfolding a topped token views it as a pair of topped tokens.

Theorem (`vUnfold.bot`). The statement bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vUnfold.pairL`). The statement pair L holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`vUnfold.pairR`). The statement pair R holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`uBot`). The u Bot.

Definition (`uForget`). The u Forget.

Definition (`uForgetInsert`). The u Forget Insert adds the payload of the matching constructor and leaves every other constructor unchanged.

Theorem (`VEnt_insert_top_imp`). Inserting the indicated constructor updates vEnt insert top imp by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_foldr_uForget`). A token lies in the mem foldr u Forget exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`not_VEnt_singleton_ne_top`). The claim not VEnt singleton ne top fails.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`not_VEnt_insert_top_of_ent`). The claim not VEnt insert top of ent fails.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`uForgetFinset`). The u Forget finite set.

Theorem (`mem_uForgetFinset`). A token lies in the mem u Forget finite set exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`uForgetFinset.empty`). The empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`uForgetFinset.insert`). Inserting the indicated constructor updates insert by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`uForgetFinset.mono`). The operation mono preserves inclusion.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`uForgetFinset.singleton`). On a singleton, singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`UCon`). The uCon.

Theorem (`UCon.singleton`). On a singleton, singleton returns the payload of that one constructor.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`UCon.subset`). The property subset passes to subsets.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`UEnt`). The uEnt.

Theorem (`UEnt.bot`). The statement bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`UEnt.of_mem`). The statement of mem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`UEnt.trans`). The relation trans is transitive.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`UCon_insert_of_ent`). Inserting the indicated constructor updates uCon insert of ent by adding that payload.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`uSystem`). The universal domain is the topped domain with the top element removed.

Theorem (`UCon_empty`). The uCon empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`not_mem_uForget_top`). The claim not mem u Forget top fails.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

5.9.7 Example 8.3: A universal domain

A universal domain. As a final example of building up domains recursively, we give a construction of a "universal" domain U. (The reason for the name will be explained presently.) The best way to define U seems to be to define a domain V with a top element first, and then to remove the top.

The recursion for V is remarkably simple. We begin with two distinct objects Δ and ∇ that give information about the bottom and top of V, respectively. Thus, $\Delta_V = \Delta$ by definition. We assume that these two special data objects are "atomic" in the sense that they are not equal to any ordered pair of objects. For the definition of D_V we have these clauses:

(1) $\Delta, \nabla \in D_V$;

(2) $(X, \Delta) \in D_V$ and $(\Delta, Y) \in D_V$ whenever $X, Y \in D_V$.

In other words, we begin with two objects and close up under two flavors of copies of these objects. (A product result is involved here, so that is the reason for structuring the flavors the way we have.)

For V all subsets of D_V are consistent, so all we have left is to define entailment for this domain. The clauses are:

(3) $u \vdash_V \Delta$ always;

(4) $u \vdash_V \nabla$ whenever either $\nabla \in u$ or $\{X \mid (X, \Delta) \in u\} \vdash_V \nabla$ and $\{Y \mid (\Delta, Y) \in u\} \vdash_V \nabla$;

(5) $u \vdash_V (X', \Delta)$ whenever either $\nabla \in u$ or $\{X \mid (X, \Delta) \in u\} \vdash_V X'$; and

(6) $u \vdash_V (\Delta, Y')$ whenever either $\nabla \in u$ or $\{Y \mid (\Delta, Y) \in u\} \vdash_V Y'$.

The proof that V is an information system proceeds as before. Note that, under the above definition of entailment, the data objects Δ, (Δ, Δ), $((\Delta, \Delta), \Delta)$, etc. are all equivalent. There is, however, no other data object equivalent to ∇. The domain equation satisfied by V is:

$$V \cong V \times V.$$

Of course, there are an unlimited number of solutions to this equation, so the fact that V satisfies it tells us very little.

Because ∇ entails everything, we can regard it as a "rogue" object that ought to be banned from polite company: the only element of V it gives any information about is the top element, which is as unhelpful as any element could be. We should simply throw it out as being "inconsistent." What remains is the domain U. Formally we have:

(7) $D_U = D_V - \{\nabla\}$;

(8) $\Delta_U = \Delta_V$;

(9) $\mathrm{Con}_U = \{u \subseteq D_U \mid u \text{ finite and } u \not\vdash_V \nabla\}$; and

(10) $u \vdash_U Y$ iff $u \in \mathrm{Con}_U$, $Y \in D_U$ and $u \vdash_V Y$.

The same style of definition would work in any situation when an information system has a rogue data object that entails everything: there always is a system that results from eliminating all those objects that entail everything. Indeed, we could have always included such an object in any domain and altered the definition to take as elements those deductively closed sets of data objects that *do* not have the rogue object as a member. We did not do this for the reason that superfluous elements cause lots of exceptions in constructs such as product, where there is a temptation to let them enter into various combinations.

Now in U we *do* allow ∇ to enter into combinations—and this is part of the secret of the construction. The consequence is, however, that the domain equation which U satisfies is not too easy to state since it involves an unfamiliar functor. So it is not through such equations that we will understand its nature in a direct way. But it is possible to explain how it works by reference to the steps in the construction.

Imagine the full (infinite) binary tree. The data objects of U are giving information about possible paths in the tree. We think to the tree starting at the root node at the top of the page and growing down. The object Δ gives no information—so no paths are *excluded*. (If we would have allowed ∇, then the information it would have been giving is that all paths are excluded.) The data object (X, Δ) tells us about a path that *either* it is unrestricted on the right half of the tree, *or* on the left, when we start at the node directly below the root, the paths that are excluded from the subtree are those excluded according to X. This makes sense because the subtrees of the binary tree look exactly like the whole tree, so information can be relativized or translated to other positions. With (Δ, Y) the rôles of right and left are interchanged. We could have introduced data objects of the form (X, Y) which tell us information about both halves of the tree at the same time, but the consistent set $\{(X, \Delta), (\Delta, Y)\}$ does the same job. In general consistent sets should be thought of as *conjunctions*; while, in this example, the comma in the ordered pair should be thought of as a *disjunction* when "reading" information objects.

We can now see that a single data object (if it contains ∇) looks down the tree along a finite path to some depth and then *excludes* the rest of the tree below that node. A consistent set of data objects leaves at least one hole, so at least one path is not excluded. The maximal consistent sets of information objects are those giving true information about one single (infinite) path—the total elements of the domain U correspond exactly to the infinite paths in the binary tree. The partial elements are harder to describe geometrically, however. In accumulating information into a consistent set, holes can be left all over the tree. A partial object is therefore of an indeterminate character, since the "path" we are describing might sneak through any one of the holes. (There is, by the way, a precise topological explanation of what is happening. The total elements of U form a well-known topological space, the so-called Cantor space, and the partially ordered set of elements of U is isomorphic to the lattice of *open* sets of the space—save that the whole space is not allowed.)

This is all very well, but what, we ask, is the good of this domain, and why is it called "universal". The proof cannot be given here, but the result is as follows. As a consequence of standard facts about countable Boolean algebras, it can be proved that every "countably based" domain is a subdomain of U. More specifically, if $\mathbf{A}$ is an information system, and if $D_{\mathbf{A}}$ is countable, then there exists a pair of approximable mappings

$$a : \mathbf{A} \to \mathbf{U} \text{ and } b : \mathbf{U} \to \mathbf{A},$$

such that

$$b \circ a = I_{\mathbf{A}} \text{ and } a \circ b \subseteq I_{\mathbf{U}}.$$

This makes $\mathbf{A}$ a special kind of retract of $\mathbf{U}$. The mappings a and b are far from unique, but at least there is one way to give a one-one embedding of the elements of $\mathbf{A}$ into the elements of $\mathbf{U}$.

The universal property of $\mathbf{U}$ can be applied quite widely. For example, since $(\mathbf{U} \to \mathbf{U})$ is a system with only countably many data objects (by explicit construction!), this system is a retract of $\mathbf{U}$. Fixing on one such retraction pair as above, makes $\mathbf{U}$ also into a model of the λ-calculus. Whether different retractions give essentially different models I do not know. But the point of the remark is to show that domains can contain their own function spaces for a variety of interesting reasons. ?

Theorem (`example_8_3`). The empty set of tokens of the universal domain is consistent.

Proof. Empty consistency is the base clause of consistency for the universal domain. ?

5.9.8 Approximations of domains

Definition (`PEnt`). Entailment in the powerset holds when the output integer already belongs to the input finite set.

Definition (`bar`). The bar.

Definition (`P`). The powerset domain has the natural numbers as tokens, every finite set consistent, and the least entailment.

Theorem (`P.AllConsistent`). The statement all Consistent holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`IdemApprox`). The idem Approx.

Definition (`ReflApprox`). The refl Approx.

Definition (`barElement`). The bar Element.

Definition (`powersetBot`). The bot Element.

Definition (`powersetTop`). The top Element.

Definition (`ConsistentApprox`). The consistent Approx.

Definition (`BotApprox`). A bottom approximation is the approximable map that entails only what the empty set entails.

Definition (`RogueApprox`). A rogue approximation relates some token to the reserved top token.

Definition (`IsDomainApprox`). The is Domain Approx are given by the listed constructors.

Definition (`DomainApprox`). A domain approximation is an approximable self-map of the powerset that is reflexive, transitive, and not rogue.

Definition (`flatRel`). The flat relation on the powerset is the least entailment.

Theorem (`flatRel.empty`). The empty of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`flatRel.of_mem_one`). The statement of mem one holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_barElement`). A token lies in the mem bar Element exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`mem_topElement`). A token lies in the mem top Element exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`scottCon`). The scott Con.

Theorem (`BotApprox_any`). The statement bot Approx any holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`flatMap`). The flat map is the approximable map of the least entailment.

Theorem (`flatMap.consistent`). The statement consistent holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`flatMap.idem`). The statement idem holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`flatMap.refl`). The statement refl holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`flatMap.toElement_of_mem_one`). The statement to Element of mem one holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`flatMap.rogue`). The statement rogue holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`flatMap.isDomain`). The statement is Domain holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Definition (`flatDomainApprox`). The flat Domain Approx.

Theorem (`mem_botElement`). A token lies in the mem bot Element exactly when a matching constructor in the set contributes it.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`not_RogueApprox_idMap`). The claim not Rogue Approx id Map fails.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`barElement_zero_eq_bot`). The equality bar Element zero eq bot holds.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

Theorem (`scottCon_empty_iff_consistent`). The scott Con empty iff consistent of the empty set is empty.

Proof. By cases on the constructors, or by the matching clause of consistency or entailment. ?

5.9.9 Example 8.4: A domain of domains

A domain of domains. Not many details can be presented here, but we would also like to remark that even domains can be made into a domain. One way of getting an idea of how this is possible is to note that since subdomains of $\mathbf{U}$ correspond to certain kinds of functions on $\mathbf{U}$, and since the function space of $\mathbf{U}$ is also a subdomain of $\mathbf{U}$, it might be suspected that the subdomains of $\mathbf{U}$ form a single subdomain of $\mathbf{U}$.

That is a fairly sophisticated way of reaching the conclusion (and many details have to be worked out). A more elementary approach would be just to ask what it means to give a finite amount of information about a domain. For the sake of uniformity, suppose that the data objects of the possible domain are drawn from the non-negative integers, and that we conventionally use 0 for Δ. Then to give a finite amount of information about a domain is—roughly—to specify a finite part of Con and a finite part of $\vdash$. To make the formulation easier, we will reserve for 1 a rôle like the one recently played by ∇. What the specifications will boil down to is pairs (u, v) of finite sets of integers used as data objects to convey one piece of information about an entailment relation.

But hold, entailment relations are very closely connected to approximable mappings. Indeed, we remarked before that the identity function as an approximable mapping on a domain is just represented as the underlying entailment relation itself. Suppose we take as our domain the domain of all sets of integers. It is a powerset, so call it $\mathbf{P}$. That is to say, the integers are the data objects, all finite sets are consistent, and the entailment relation is the minimal possible one. (As far as elements go, an arbitrary set of integers is equal to the union of all its finite subsets, which means that the elements of the domain are in a one-one correspondence with the arbitrary sets of integers.) The question is: which approximable mappings on $\mathbf{P}$ into itself correspond to entailment relations on the integers as data objects?

The answer can be expressed most succinctly using our standard notation. If we think of $r : \mathbf{P} \to \mathbf{P}$ as a relation between finite sets in the usual way, then to say that r is reflexive is to say:

(1) $I_{\mathbf{P}} \subseteq r$.

To say that r is transitive is to say:

(2) $r \circ r = r$.

To say that for r the object 0 plays at being Δ is to say:

$$(3) \quad \bar{0} \subseteq r(\bot),$$

where in general $\bar{n}$ is short for $\{n\}$ in the domain $\mathbf{P}$. Then, to say that 1 plays at being a rogue object is to say:

$$(4) \quad \top = r(\bar{1}).$$

Finally, to say that 1 is an inconsistent object that has to be excluded is to say:

$$(5) \quad \bar{1} \not\subseteq r(\bar{0}).$$

That's it. The collection of approximable mappings satisfying (1)–(5) gives us all the entailment relations we need. Condition (5) is a consistency condition, and for r the consistent finite sets u are those such that $\bar{1} \not\subseteq r(\bar{u})$. What we are asserting is that the totality of r satisfying (1)–(5) forms the elements of a domain—one that has been derived from $(\mathbf{P} \to \mathbf{P})$ in a way similar to the way we derived $\mathbf{U}$ from $\mathbf{V}$ above.

Having made domains into a domain, the next step is to see how constructs on domain (i.e. functors) can be made into approximable mappings. But the retelling and development of that story will have to wait for another publication along with the very interesting chapter on powerdomains. I only hope the ground covered here makes the theory of domains seem more elementary and more natural. ?

Theorem (`example_8_4`). The identity map on the powerset of the integers is not a rogue approximation.

Proof. The identity is reflexive, so it fails the rogue clause. ?

`example_8_4.lean`

6 Bridge Theorems

<!DOCTYPE svg PUBLIC “-//W3C//DTD SVG 1.1//EN” “http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd”>

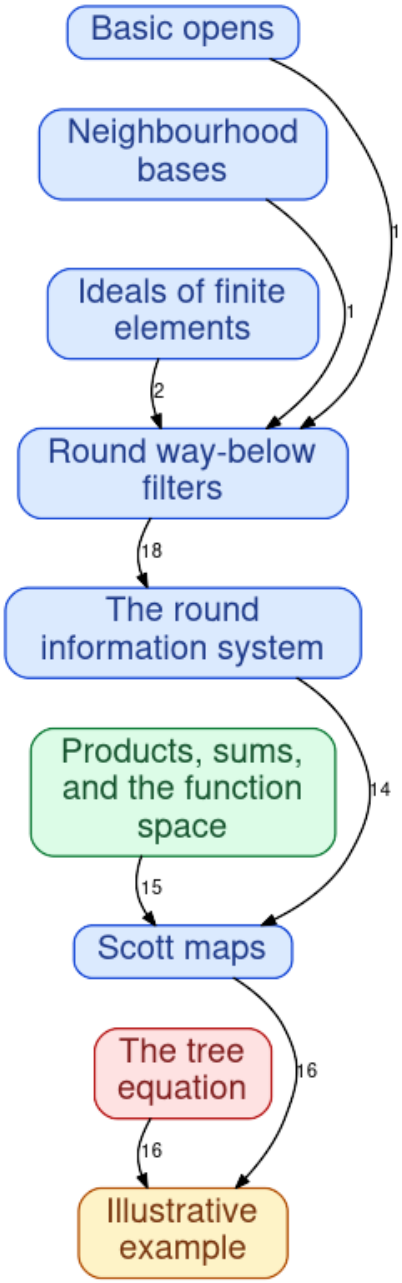

Figure 63: Diagram 28

6.1 Introduction

Neighbourhood systems and information systems are equivalent in a precise sense. The mathematical folklore is stronger still: all three presentations carve out the same class of domains, related by ideal completion and the Scott topology. That equivalence is already known; this article is the write-up of a machine-checked proof of the named bridges, not a first presentation of the result. The three presentations were formalized in separate libraries; the maps between them are the content of this package.

We do **not** re-prove Scott's internal theorems; we import the finished sibling packages and build cross-presentation maps:

Presentation	Lean package	Characteristic object
Continuous lattices [1]	`scott1972`	`ContinuousLattice D`, way-below $\ll$, `ScottMap`
Neighbourhood systems [2]	`scott1980`	`NeighborhoodSystem`, filters as domain elements
Information systems [3]	`scott1982`	`InfoSys`, elements as consistent closed token sets

The main subtlety is that a naïve reading of "domains = filters of neighbourhoods" overstates the continuous-lattice corner: for a continuous lattice `D`, the filter `{⇑a | a ≤ x}` has retract `x` but properly contains the principal round filter `{⇑a | a ≪ x}`. The correct identification is **`D ≃o RoundFilter`**, not raw $|\mathcal{D}|$.

<!DOCTYPE svg PUBLIC "-//W3C//DTD SVG 1.1//EN" "http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd">

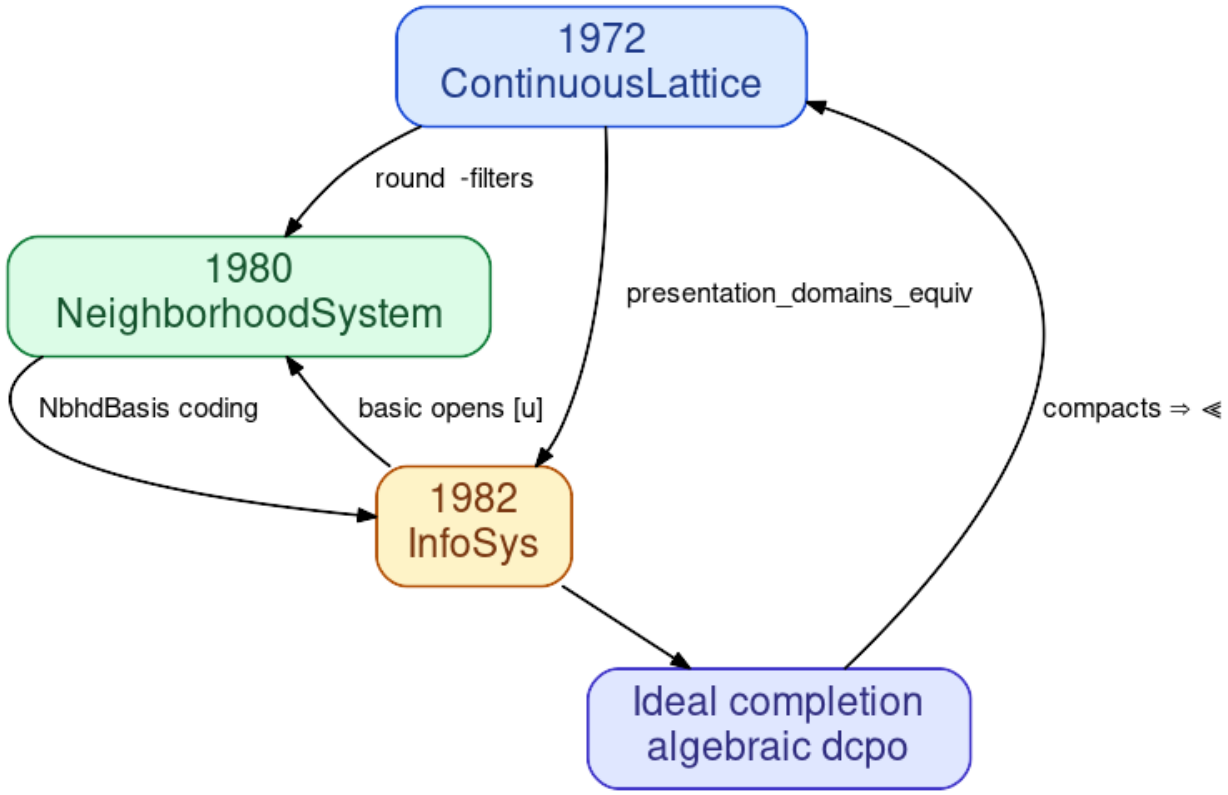

Figure 64: Diagram 29

The bridges are order isomorphisms of domains, and of the named construction objects, in `DomainTheory.BridgeTh` They are not a 2-categorical equivalence of the full categories of continuous lattices, neighbourhood systems, and information systems with all morphisms.

The three presentation-to-presentation bridges (year labels = source → target of the packaged order isomorphism):

Label	Years	Statement	Declaration	Note
`bridge_1972_1980`	1972 → 1980	A continuous lattice `D` is order-isomorphic to its round way-below filters.	`continuousLattice_roundFilter_iso` (= `ContinuousLattice.roundFilterEquiv`)	Round way-below filters / Packaging the round-filter isomorphism
`bridge_1980_1982`	1980 → 1982	Filters of a neighbourhood basis are order-isomorphic to elements of the induced information system.	`NbhdBasis.domainEquivInfo` (system via `neighborhoodSystem_to_infoSys`)	Neighbourhood bases / Neighbourhood filters and information-system elements

Label	Years	Statement	Declaration	Note
bridge_1982_1972	1982 → 1972	Elements of an information system are order-isomorphic to ideals of its finite elements (algebraic / 1972 carrier).	infoSys_to_idealCompletion	Ideals of finite elements / The ideal completion of an information system

Related companions (same chapter, not the three year-pair labels above):

Bridge	Statement	Declaration
1982 → 1980 (basic opens)	An information system induces the neighbourhood system of its basic opens; elements ≃o filters of that system.	infoSys_to_neighborhoodSystem, InfoSysToNeighborhood.domainOrderI
Neighbourhood system of way-below opens	The neighbourhood system associated with a continuous lattice.	continuousLattice_to_neighborhoodSystem
Algebraic lattices	An algebraic complete lattice is a continuous lattice.	idealCompletion_to_continuousLattice
Round three-way identification	For a continuous lattice with decidable equality, D ≃o RoundInfoSysElement, through D ≃o RoundFilter ≃o RoundInfoSysElement.	presentation_domains_equiv

Products, sums, the function space, and Scott maps are collected under infoSys_constructions_equiv:

Construction	Statement	Declaration
Product	|A| × |B| ≃o |A × B|	infoSys_product_domain_equiv
Sum	WithBot (|A| ⊕ |B|) ≃o |A + B|	infoSys_sum_domain_equiv
Function space	Approximable maps A → B are order-isomorphic to the elements of the function-space system.	infoSys_function_space_domain_equiv

Construction	Statement	Declaration
Scott continuity	Approximable maps `A → B` are order-isomorphic to the Scott-continuous maps on elements.	`approximableMap_scottContinuous_equiv`
Scott maps, round filters	Scott maps of continuous lattices are order-isomorphic to their conjugates along `D ≃o RoundFilter`.	`scottMap_roundFilter_iso`
Scott maps, round information systems	The same, along `presentation_domains_equiv`.	`scottMap_roundInfoSys_iso`

On Scott's tree domain over the lower-bound system of the natural numbers, the same carrier is an information system, a neighbourhood-filter domain, and an ideal completion, and it satisfies the equation `T ≅ A + (T × T)` as an order isomorphism of elements:

Instance	Statement	Declaration
Neighbourhood filters	`SexSys.Element ≃o` the filters of its basic-open neighbourhood system	`sexNeighborhoodIso`
Ideals	`SexSys.Element ≃o` the ideals of its finite elements	`sexIdealIso`
Domain equation	`SexSys.Element ≃o SexRhs.Element`	`sexDomainEquationIso`

A full functorial equivalence, preserving products, exponentials, and inverse limits simultaneously across all three presentations, would require additional coherence theorems.

Where Scott's 1982 text is constructive, the bridges stay constructive. Classical steps are named. The continuous-lattice identification `D ≃o RoundFilter` uses only propositional extensionality and quotient soundness: roundness is a condition on the order. An algebraic lattice is a continuous lattice by the 1972 definition of way-below, which is classical. Separated sums use classical choice for the polarity of a token (left, right, or bottom). Conjugation of Scott maps inherits that choice from the 1972 development of `ScottMap`.

Every other information-system bridge reports `Classical.choice` as well, but only because Mathlib's `Finset` instances depend on it. A declaration whose type mentions an information system therefore prints choice even when the proof manipulates an explicit finite set and extracts no witness. That is the footprint of neighbourhood bases in both directions, of ideals of finite elements, of products and function spaces, and of approximable maps against Scott-continuous maps. The separated-sum trichotomy is a use of choice; those others are the instance frontier.

6.2 Basic opens

<!DOCTYPE svg PUBLIC "-//W3C//DTD SVG 1.1//EN" "http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd">

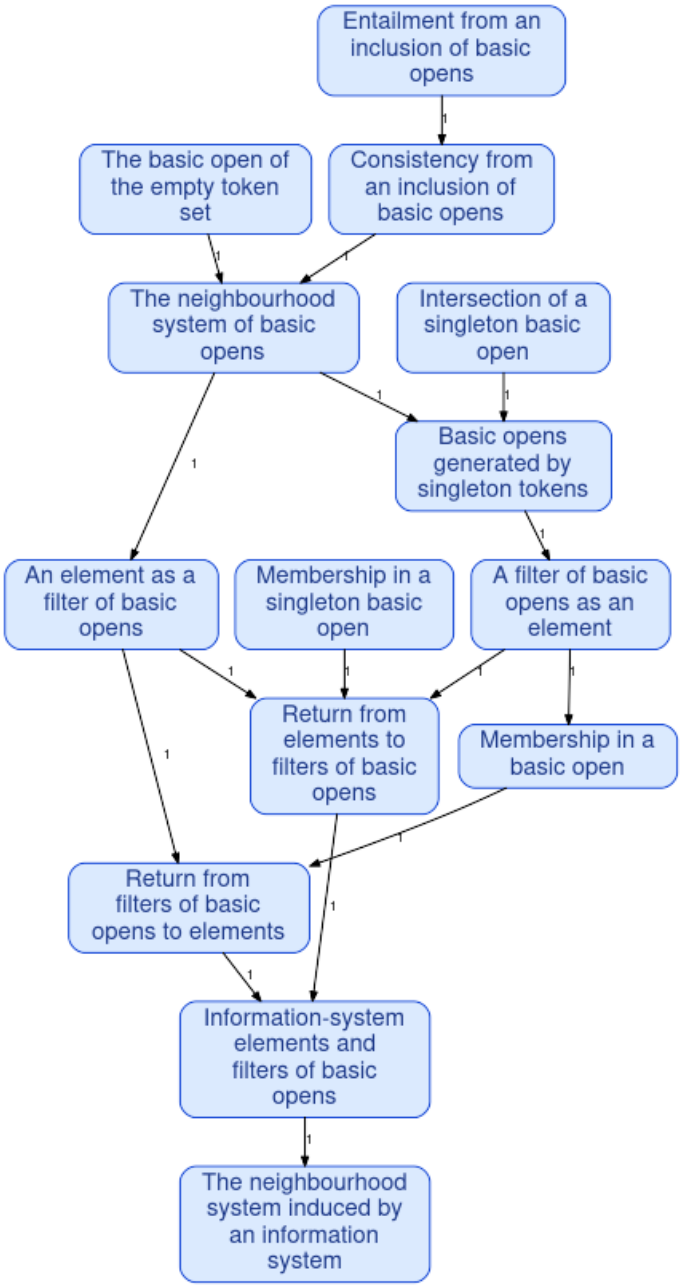

Figure 65: Diagram 30

6.2.1 The basic open of the empty token set

Theorem (`basicOpen_empty`). In an information system, the basic open determined by the empty token set is the whole set of elements.

Proof. Membership in that basic open asks that every token of the empty set lie in the carrier, which is vacuously true for every element. ■

`basicOpen_empty.lean`

```
module
public import DomainTheory.InformationSystems.DomainsAsLatticesAndAsTopologicalSpaces.
    basicOpen

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems

namespace InfoSysToNeighborhood

variable {α : Type*} [DecidableEq α] (A : InfoSys α)

theorem basicOpen_empty : A.basicOpen (∅ : Finset α) = (Set.univ : Set A.Element) := by
  ext x
  constructor
  · intro; trivial
  · intro _ a ha
    exact False.elim (Finset.notMem_empty a (Finset.mem_coe.1 ha))

end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.2 Intersection of a singleton basic open

Theorem (`basicOpen_singleton_inter`). The intersection of the basic open of a singleton token with the basic open of a finite set equals the basic open of the insertion of that token into the set.

Proof. Intersection of basic opens is the basic open of the constructive union, and adjoining a singleton is insertion. ■

`basicOpen_singleton_inter.lean`

```
module
public import DomainTheory.InformationSystems.DomainsAsLatticesAndAsTopologicalSpaces.
    basicOpen
public import DomainTheory.InformationSystems.InformationSystems.Constructive.funion

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems

open DomainTheory.InformationSystems.Constructive

open DomainTheory.InformationSystems.InfoSys

namespace InfoSysToNeighborhood

variable {α : Type*} [DecidableEq α] (A : InfoSys α)

theorem basicOpen_singleton_inter (a : α) (s : Finset α) :
```

```
    A.basicOpen ({a} : Finset α) ∩ A.basicOpen s = A.basicOpen (insert a s) := by
  rw [basicOpen.inter A, funion.singleton_eq_insert]

end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.3 Membership in a singleton basic open

Theorem (`mem_basicOpen_singleton`). An element belongs to the basic open of a singleton token if and only if that token lies in its carrier.

Proof. The basic-open condition for a singleton reduces to membership of that unique token. ■

`mem_basicOpen_singleton.lean`

```
module
public import DomainTheory.InformationSystems.DomainsAsLatticesAndAsTopologicalSpaces.
    basicOpen

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems

namespace InfoSysToNeighborhood

variable {α : Type*} [DecidableEq α] (A : InfoSys α)

theorem mem_basicOpen_singleton {a : α} {x : A.Element} :
    x ∈ A.basicOpen ({a} : Finset α) ↔ a ∈ x.carrier := by
  constructor
  · intro h
    exact h (Finset.mem_coe.2 (Finset.mem_singleton_self a))
  · intro ha b hb
    have hb' : b = a := Finset.mem_singleton.mp (Finset.mem_coe.1 hb)
    exact hb' ▸ ha

end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.4 Entailment from an inclusion of basic opens

Theorem (`ent_of_basicOpen_subset`). If a consistent finite set w has its basic open contained in the basic open of u, then every token of u is entailed by w.

Proof. The closure of w lies in the basic open of w, hence in that of u, so every token of u belongs to the closure and is therefore entailed by w. ■

`ent_of_basicOpen_subset.lean`

```
module
```

```
public import DomainTheory.InformationSystems.DomainsAsLatticesAndAsTopologicalSpaces.
    basicOpen

open DomainTheory.InformationSystems.InfoSys

namespace InfoSysToNeighborhood

variable {α : Type*} [DecidableEq α] (A : InfoSys α)

theorem ent_of_basicOpen_subset {u w : Finset α} (hw : w ∈ A.Con)
    (hsub : A.basicOpen w ⊆ A.basicOpen u) {a : α} (ha : a ∈ u) : A.Ent w a := by
  have : A.closure w hw ∈ A.basicOpen w := closure.subset A hw
  have hU : A.closure w hw ∈ A.basicOpen u := hsub this
  exact hU (Finset.mem_coe.2 ha)

end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.5 Consistency from an inclusion of basic opens

Theorem (`con_of_basicOpen_subset`). If a consistent finite set w has its basic open contained in the basic open of u, then u is consistent.

Proof. Every token of u is entailed by w, so the constructive union of w with u is consistent, and consistency passes to subsets. ■

`con_of_basicOpen_subset.lean`

```
module
public import DomainTheory.InformationSystems.DomainsAsLatticesAndAsTopologicalSpaces.
    basicOpen
public import DomainTheory.BridgeTheorems.ent_of_basicOpen_subset

open DomainTheory.InformationSystems.Constructive

open DomainTheory.InformationSystems.InfoSys

namespace InfoSysToNeighborhood
```

```
variable {α : Type*} [DecidableEq α] (A : InfoSys α)

theorem con_of_basicOpen_subset {u w : Finset α} (hw : w ∈ A.Con)
    (hsub : A.basicOpen w ⊆ A.basicOpen u) : u ∈ A.Con := by
  have hEnt : A.EntSet w u := fun a ha => ent_of_basicOpen_subset A hw hsub ha
  exact A.con_subset (EntSet.union_mem A hw hEnt) (funion.subset_right _ _)

end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.6 The neighbourhood system of basic opens

Definition (`toNeighborhoodSystem`). The neighbourhood system associated with an information system has as neighbourhoods precisely the basic opens of consistent finite token sets, with the whole set of elements as master neighbourhood.

The empty set is consistent and determines the master neighbourhood. The intersection of two basic opens is the basic open of their constructive union, which remains consistent whenever a third basic open sits below both.

`toNeighborhoodSystem.lean`

```
module
public import DomainTheory.InformationSystems.DomainsAsLatticesAndAsTopologicalSpaces.
    basicOpen
public import DomainTheory.NeighbourhoodSystems.DomainsGivenByNeighbourhoods.
    NeighborhoodSystem

variable {α : Type*} [DecidableEq α] (A : InfoSys α)

def toNeighborhoodSystem : NeighborhoodSystem A.Element where
  mem X := ∃ u, u ∈ A.Con ∧ X = A.basicOpen u
  master := Set.univ
  master_nonempty := ⟨A.closure ∅ A.con_empty, Set.mem_univ _⟩
  master_mem := ⟨∅, A.con_empty, (basicOpen_empty A).symm⟩
  inter_mem := by
    intro X Y Z hX hY hZ hZsub
    obtain ⟨u, hu, rfl⟩ := hX
```

```
    obtain ⟨v, hv, rfl⟩ := hY
    obtain ⟨w, hw, rfl⟩ := hZ
    have hsub : A.basicOpen w ⊆ A.basicOpen (u ∪' v) := by
      intro x hx
      have hx' : x ∈ A.basicOpen u ∩ A.basicOpen v := hZsub hx
      rwa [basicOpen.inter A] at hx'
    have huv : u ∪' v ∈ A.Con := con_of_basicOpen_subset A hw hsub
    exact ⟨u ∪' v, huv, basicOpen.inter A u v⟩
  sub_master := fun {_} _ => Set.subset_univ _

end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.7 Basic opens generated by singleton tokens

Theorem (`mem_basicOpen_of_singletons`). A filter of the basic-open neighbourhood system that contains every singleton basic open for tokens of a finite set also contains the basic open of that set.

Proof. By induction on the finite set: the empty case is the master neighbourhood, and the inductive step uses closure of filters under intersection together with the singleton-intersection identity for basic opens. ■

`mem_basicOpen_of_singletons.lean`

```
module

public import DomainTheory.BridgeTheorems.toNeighborhoodSystem

    simpa [basicOpen_singleton_inter A a s] using f.inter_mem hA hSm
```

```
end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.8 An element as a filter of basic opens

Definition (`toFilter`). From an element of an information system one obtains a filter of the basic-open neighbourhood system by taking those basic opens of consistent finite sets whose tokens all lie in the element's carrier.

Subset neighbourhoods, the master neighbourhood, intersections, and upward closure follow from consistency and deductive closure of the element together with the corresponding facts for basic opens.

`toFilter.lean`

```
module

    intro a ha
    exact x.closed u a huX (ent_of_basicOpen_subset A hu hUV ha)

end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.9 A filter of basic opens as an element

Definition (`ofFilter`). From a filter of the basic-open neighbourhood system one recovers an element whose carrier consists of those tokens whose singleton basic opens belong to the filter.

Consistency of finite subsets of the carrier follows from membership of the corresponding basic open and the criterion that inclusions of basic opens preserve consistency; deductive closure uses upward closure of the filter under inclusions of basic opens.

`ofFilter.lean`

```
module

public import DomainTheory.BridgeTheorems.toNeighborhoodSystem
public import DomainTheory.NeighbourhoodSystems.DomainsGivenByNeighbourhoods.Element
public import DomainTheory.BridgeTheorems.con_of_basicOpen_subset

    exact f.up_mem hmemY ⟨({b} : Finset α), A.con_sing b, rfl⟩ hsub

end InfoSysToNeighborhood

end DomainTheory.BridgeTheorems
```

6.2.10 Membership in a basic open

Theorem (`mem_basicOpen_iff`). A filter of the basic-open neighbourhood system contains the basic open of a consistent finite set if and only if every token of that set lies in the carrier of the element recovered from the filter.

Proof. One direction uses upward closure under inclusions of singleton basic opens; the other assembles singleton memberships into membership of the joint basic open. ■

`mem_basicOpen_iff.lean`

```
module

public import DomainTheory.BridgeTheorems.ofFilter

```

6.2.13 Information-system elements and filters of basic opens

Definition (`domainOrderIso`). The maps sending an information-system element to its filter of basic opens and a filter back to an element form an order isomorphism between the elements of the information system and the filters of its basic-open neighbourhood system.

The two composites are the identity by the round-trip theorems; order is preserved because inclusion of carriers is equivalent to inclusion of the associated filters of basic opens.

domainOrderIso.lean

    NeighborhoodSystem A.Element :=
  InfoSysToNeighborhood.toNeighborhoodSystem A

end DomainTheory.BridgeTheorems
```

6.3 Neighbourhood bases

<!DOCTYPE svg PUBLIC “-//W3C//DTD SVG 1.1//EN” “http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd”>

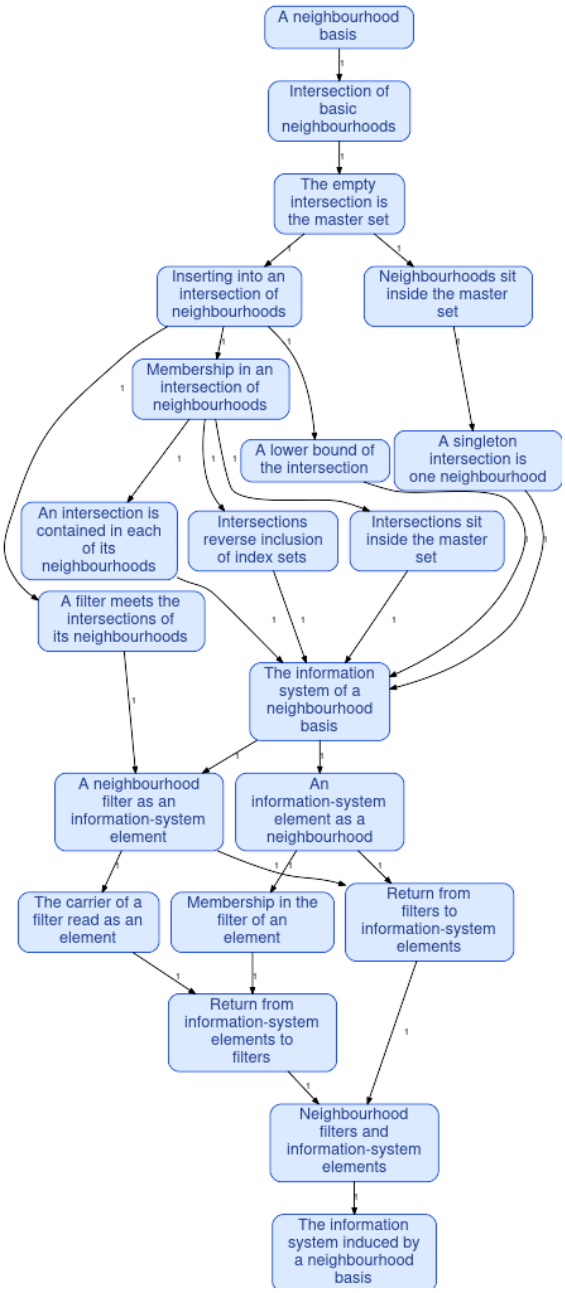

Figure 66: Diagram 31

6.3.1 A neighbourhood basis

Definition (`NbhdBasis`). A neighbourhood basis for a neighbourhood system indexes every neighbourhood by a token from an index type, with a distinguished bottom index whose neighbourhood is the master set.

Every basic neighbourhood is a neighbourhood of the system, and every neighbourhood arises as some basic neighbourhood.

NbhdBasis.lean

```
module
public import DomainTheory.NeighbourhoodSystems.DomainsGivenByNeighbourhoods.
    NeighborhoodSystem

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.NeighbourhoodSystems

structure NbhdBasis (ι α : Type*) [DecidableEq ι] where
  system : NeighborhoodSystem α
  nbhd : ι → Set α
  nbhd_mem : ∀ i, system.mem (nbhd i)
  exhaustive : ∀ {X : Set α}, system.mem X → ∃ i, nbhd i = X
  botIdx : ι
  botIdx_eq : nbhd botIdx = system.master

end DomainTheory.BridgeTheorems
```

6.3.2 Intersection of basic neighbourhoods

Definition (`interOf`). The intersection of the basic neighbourhoods indexed by a finite set of tokens, taken inside the master set.

interOf.lean

```
module

public import Mathlib.Data.Finset.Fold
public import DomainTheory.BridgeTheorems.NbhdBasis

@[expose] public section

namespace DomainTheory.BridgeTheorems

namespace NbhdBasis

variable {ι α : Type*} [DecidableEq ι] (B : NbhdBasis ι α)

def interOf (u : Finset ι) : Set α :=
  u.fold (· ∩ ·) B.system.master B.nbhd

end NbhdBasis

end DomainTheory.BridgeTheorems
```

6.3.3 The empty intersection is the master set

Theorem (`interOf_empty`). The intersection over the empty index set is the master neighbourhood.

Proof. An empty intersection inside the master set is the master set itself. ■

interOf_empty.lean

```
module

public import DomainTheory.BridgeTheorems.interOf

@[expose] public section

@[simp] theorem interOf_empty : B.interOf (∅ : Finset ι) = B.system.master := rfl

end NbhdBasis

end DomainTheory.BridgeTheorems
```

6.3.4 Neighbourhoods sit inside the master set

Theorem (`nbhd_subset_master`). Every basic neighbourhood is contained in the master set.

Proof. Neighbourhoods of a neighbourhood system sit under the master set. ■

nbhd_subset_master.lean

```
module

public import DomainTheory.BridgeTheorems.NbhdBasis

@[expose] public section

namespace DomainTheory.BridgeTheorems

namespace NbhdBasis

variable {ι α : Type*} [DecidableEq ι] (B : NbhdBasis ι α)

theorem nbhd_subset_master (i : ι) : B.nbhd i ⊆ B.system.master :=
  B.system.sub_master (B.nbhd_mem i)

end NbhdBasis

end DomainTheory.BridgeTheorems
```

6.3.5 Inserting into an intersection of neighbourhoods

Theorem (`interOf_insert`). Inserting a token into a finite index set intersects the corresponding basic neighbourhood with the previous intersection.

Proof. This is the usual decomposition of a finite intersection. ■

interOf_insert.lean

```
module

public import DomainTheory.BridgeTheorems.interOf

@[expose] public section

namespace DomainTheory.BridgeTheorems

namespace NbhdBasis

variable {ι α : Type*} [DecidableEq ι] (B : NbhdBasis ι α)

theorem interOf_insert {a : ι} {s : Finset ι} (ha : a ∈ s) :
    B.interOf (insert a s) = B.nbhd a ∩ B.interOf s :=
  Finset.fold_insert (op := (· ∩ ·)) ha

end NbhdBasis

end DomainTheory.BridgeTheorems
```

6.3.6 A singleton intersection is one neighbourhood

Theorem (`interOf_singleton`). The intersection over a singleton index is that basic neighbourhood.

Proof. Immediate from the definition of the finite intersection. ■

`interOf_singleton.lean`

```
module

public import DomainTheory.BridgeTheorems.interOf
import DomainTheory.BridgeTheorems.nbhd_subset_master

@[expose] public section

namespace DomainTheory.BridgeTheorems

namespace NbhdBasis

variable {ι α : Type*} [DecidableEq ι] (B : NbhdBasis ι α)

theorem interOf_singleton (a : ι) : B.interOf ({a} : Finset ι) = B.nbhd a := by
  simp [interOf, Finset.fold_singleton, Set.inter_eq_left.mpr (B.nbhd_subset_master a)
    ]

end NbhdBasis

end DomainTheory.BridgeTheorems
```

6.3.7 A lower bound of the intersection

Theorem (`interOf_mem_of_lower_bound`). If a neighbourhood is contained in the intersection of the basic neighbourhoods of a finite index set, then that intersection is itself a neighbourhood.

Proof. Neighbourhood systems are upward closed: a set containing a neighbourhood is a neighbourhood. ■

`interOf_mem_of_lower_bound.lean`

```
module

public import DomainTheory.BridgeTheorems.interOf
import DomainTheory.BridgeTheorems.interOf_empty
import DomainTheory.BridgeTheorems.interOf_insert

@[expose] public section

namespace ContinuousLatticeToNeighborhood

variable {D : Type*} [CompleteLattice D]

def wayBelowUp (a : D) : Set D := {z | a ≪ z}

end ContinuousLatticeToNeighborhood

end DomainTheory.BridgeTheorems
```

6.5.2 The way-below open of the bottom

Theorem (`wayBelowUp_bot`). The way-below open of the bottom element is the whole lattice.

Proof. The bottom is way-below every element. ■

`wayBelowUp_bot.lean`

```
module

public import DomainTheory.BridgeTheorems.ContinuousLatticeToNeighborhood.wayBelowUp

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.ContinuousLattice

namespace ContinuousLatticeToNeighborhood

variable {D : Type*} [CompleteLattice D]

theorem wayBelowUp_bot : wayBelowUp (⊥ : D) = (Set.univ : Set D) := by
  ext z
  exact ⟨fun _ => trivial, fun _ => WayBelow.bot z⟩

end ContinuousLatticeToNeighborhood

end DomainTheory.BridgeTheorems
```

6.5.3 Way-below opens reverse the order

Theorem (`wayBelowUp_anti`). If $a \leq b$, then the way-below open of b is contained in that of a.

Proof. Way-below is monotone in its lower argument. ■

`wayBelowUp_anti.lean`

```
module

public import DomainTheory.BridgeTheorems.ContinuousLatticeToNeighborhood.wayBelowUp

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.ContinuousLattice

namespace ContinuousLatticeToNeighborhood

variable {D : Type*} [CompleteLattice D]

theorem wayBelowUp_anti {a b : D} (hab : a ≤ b) :
    wayBelowUp b ⊆ wayBelowUp a :=
  fun _ h => WayBelow.le_trans hab h

end ContinuousLatticeToNeighborhood

end DomainTheory.BridgeTheorems
```

6.5.4 Intersection of way-below opens

Theorem (`wayBelowUp_inter`). The intersection of the way-below opens of a and b is the way-below open of their join.

Proof. A point is way-above both a and b if and only if it is way-above their join. ■

`wayBelowUp_inter.lean`

```

6.10 Illustrative example

<!DOCTYPE svg PUBLIC “-//W3C//DTD SVG 1.1//EN” “http://www.w3.org/Graphics/SVG/1.1/DTD/svg11.dtd”>

Figure 73: Diagram 38

Landings for the S-expression / tree domain (`SexSys` over `lowerBoundSystem`). These are the compared endpoints of the example; everything else in this section builds or unpacks them.

Landing	Claim	Where
`sexNeighborhoodIso`	`SexSys.Element` ≃o filters of basic opens (**1982 ≃o 1980**)	Neighbourhood filters, ideals, and the identity
`sexIdealIso`	`SexSys.Element` ≃o `Ideal (FiniteElement SexSys)` (**1982 ≃o algebraic / 1972 carrier**)	same note
`sexNeighborhoodIdealIso`	filters ≃o ideals (**1980 ≃o 1972 carrier**), closing the triangle	same note
`sexDomainEquationIso`	`SexSys.Element` ≃o `SexRhs.Element` (**`T ≃o A + (T × T)`**)	The tree equation as an order isomorphism
`exists_ sexNeighborhoodIso`	nonempty wrapper for the neighbourhood landing	Existence of the neighbourhood-filter isomorphism
`exists_sexIdealIso`	nonempty wrapper for the ideal landing	Existence of the ideal isomorphism
`exists_ sexDomainEquationIso`	nonempty wrapper for the domain equation	Existence of the tree-equation isomorphism

Secondary (not the compared fixed-point landing): `sexRhsSemanticIso` is the generic semantic factor `WithBot (|A| ⊕ (|T| × |T|)) ≃o |A + (T × T)|` in The semantic factor of the separated sum.

6.10.1 The tree domain in three presentations

Landings (read this first) On this example the compared endpoints are three order isomorphisms of carriers, plus one domain equation. Their Lean homes in this barrel:

Landing	Years	Lean	Note
`sexNeighborhoodIso`	1982 ≃o 1980	`WorkedExampleSExpr.lean`	specialises `InfoSysToNeighborhood.domain`
`sexIdealIso`	1982 ≃o 1972 carrier	`WorkedExampleSExpr.lean`	specialises `InfoSysToIdealCompletion.dom`
`sexNeighborhoodIdealIso`	1980 ≃o 1972 carrier	`WorkedExampleSExpr.lean`	specialises `neighborhood_ ideal_iso`
`sexDomainEquationIso`	T ≃o A+(T×T)	`WorkedExampleSExpr.lean`	specialises `treeDomainIso`

Existence wrappers (`exists_sexNeighborhoodIso`, `exists_sexIdealIso`, `exists_sexDomainEquationIso`) live in the matching `exists_sex*.lean` notes. The uncompared semantic factor `sexRhsSemanticIso` is **not** a landing of the fixed-point equation.

Lean packaging: `WorkedExampleSExpr.lean`, `SexDomainEquation.lean`. The Palomar compared family includes `sexNeighborhoodIso`, `sexIdealIso`, and `sexDomainEquationIso` (Challenge / `comparator.json`). The compared domain-equation declaration is the order isomorphism `SexSys.Element ≃o SexRhs.Element` (`|T| ≃o |A + (T × T)|`), not the generic semantic factor `WithBot (|A| ⊕ (|T| × |T|)) ≃o |A + (T × T)|`.

Overview The bridges of §§2–3 are abstract. This section fixes **one** concrete domain — Scott's S-expression / tree equation `T ≅ A + (T × T)` ([3], Factoid 8.1) over the ℕ lower-bound atom system (Factoid 2.4) — and asks what that domain looks like in each paradigm:

Paradigm	What an element of `T` is
1982	a consistent, deductively closed set of tree tokens
1980	a filter of basic opens `[u]` on that token domain
1972	a point of an algebraic continuous lattice (ideal of finite elements)

We build the domain natively as an information system (§5.2), then **read the same carrier** as a neighbourhood system (§5.3) and as a continuous lattice (§5.4). Section 5.5 exhibits the order isomorphisms for this instance — so that, on S-expressions,

`T_1982 ≃o T_1980 ≃o Ideal(K(T))` and `Ideal(K(T))` is a continuous lattice,

hence transitively `T_1982 ≃o T_1980` and (via the algebraic ⇒ continuous frontier) the 1972 presentation of the same domain. Order isomorphism is an equivalence relation, so the three presentations determine one domain up to ≃o. Section 5.6 records two extras that live on top of the carriers: the domain equation at the level of domains, and identity as a morphism in both the approximable-map and Scott-continuous languages.

Information system (1982) Atoms are propositions `n ≤ x` on $\mathbb{N}$ (`lowerBoundSystem`). The tree system `SexSys := treeSystem lowerBoundSystem` has inductive tokens `TreeToken ℕ` (`bot` / `atom` / `pairL` / `pairR`). Consistency and entailment are Scott's sum×product clauses; Factoid 8.1 records that this is literally the information system of the right-hand side `A + (T × T)`:

- `SexRhs = sumSystem A (productSystem T T)` (`sexRhs_eq_sum_product`);
- token unfolding `treeUnfold` sends `atom n` to the left summand (`sexUnfold_atom`) and is a retraction onto the official sum-of-product carrier, with section `treeFold`;
- TreeEnt matches official product `ent_bot` on the two encodings of `(Δ, Δ)` (`pairL Δ` and `pairR Δ`), so closed elements are saturated for `ker(treeUnfold)`.

Finite elements include singleton atom closures `sexAtom n = ū` for `u = {atom n}`. Elements of `|T|` are the consistent closed sets of tokens — the 1982 presentation of the S-expression domain.

Neighbourhood system (1980) From `|T|` one obtains a neighbourhood system whose basic opens are `[u] = {x ∈ |T| | ↑u ⊆ x}`. In this paradigm an element of the domain is a **filter** of such opens (not a raw set of tokens). Nothing new is invented: it is the image of `SexSys` under `InfoSysToNeighborhood`. The concrete iso of §5.5 below is exactly "read each token-element as its filter of basic opens."

Continuous lattice (1972) Finite elements `K(T)` are the closures of consistent finsets. In the algebraic style that feeds Scott's 1972 theory, a domain element is an **ideal** of `K(T)` — the ideal completion of the compact basis. That poset of ideals is an algebraic complete lattice, hence a continuous lattice (`AlgebraicLattice ⇒ ContinuousLattice`, §3.5). This is the 1972 presentation of the same S-expression domain: points ordered by inclusion of ideals, with way-below recovered from the compact basis.

We do not claim a choice-free `D ≃o RoundFilter` story built from trees alone; the round ⇑-filter identification of §3.1 applies once one is already in the continuous-lattice setting.

Equivalence for this instance Specializing the bridges of §3 to `SexSys` yields order isomorphisms of carriers:

- `sexNeighborhoodIso : |T| ≃o` filters of `[u]` (`InfoSysToNeighborhood.domainOrderIso`) — **1982 ≃o 1980**;
- `sexIdealIso : |T| ≃o Ideal (FiniteElement T)` (`InfoSysToIdealCompletion.domainOr`) — **1982 ≃o algebraic / 1972 carrier**;
- `sexNeighborhoodIdealIso` (`neighborhood_ideal_iso`) — the constructive triangle closing **1980 ≃o Ideal(K(T))** without going back through tokens.

Composing any two edges recovers the third: isomorphism is transitive, so on this example the three presentations are pairwise equivalent. The 1972 corner uses the algebraic ⇒ continuous implication already flagged in §3.5 / §4. The neighbourhood ↔ information ↔ ideal triangle inherits `Classical.choice` only through the `Finset` instance frontier of §4.

Domain equation and morphisms Beyond identifying the carriers, the same example exercises constructions and maps.

Domain equation. Factoid 8.1's token unfolding `treeUnfold` (section `treeFold`) lifts to an order isomorphism of the tree domain with the official RHS domain:

`sexDomainEquationIso : SexSys.Element ≃o SexRhs.Element`

(`treeDomainIso`; `|T| ≃o |A + (T × T)|`). The maps are verified unfolding: the carrier of `sexDomainEquationIso x` is `treeUnfold '' x.carrier`, and the carrier of the inverse is the preimage `treeUnfold ⁻¹' y.carrier` (`sexDomainEquationIso_unfold` / `sexDomainEquationIso_fold`). The only non-injectivity of `treeUnfold` is Scott's two encodings of the product bottom (`pairL Δ` and `pairR Δ`); after the `ent_bot` match, closed elements are saturated for that kernel, so image and preimage invert. The generic semantic factor `WithBot (|A| ⊕ (|T| × |T|)) ≃o SexRhs.Element` is the uncompared `sexRhsSemanticIso` (classical only through the 1982 sum trichotomy); it is **not** the compared fixed-point equation.

Morphisms. The identity approximable map `idMap T` (Prop 5.4) transports along Factoid 4.6 to a Scott-continuous endomap `sexIdScottContinuous` with `toFun = id` (`sexId_toElement`) — the same endomap, named once in each morphism language.

Axioms. Object-level neighbourhood / ideal isos, `sexDomainEquationIso`, and Factoid 4.6 for `idMap` audit to `{propext, Classical.choice, Quot.sound}` through the InfoSys/`Finset` frontier of §4. The uncompared semantic factor `sexRhsSemanticIso` additionally uses the 1982 sum trichotomy.

6.10.2 The lower-bound system of the natural numbers

Definition (`lowerBoundSystem`). The lower-bound information system on the natural numbers, whose tokens are natural numbers ordered by the usual numerical order.

  SexSys.closure {TreeToken.atom n} (SexSys.con_sing _)

end DomainTheory.BridgeTheorems
```

6.10.6 The tree equation as an order isomorphism

Definition (`sexDomainEquationIso`). The order isomorphism between elements of the tree system and elements of its separated-sum-of-product right-hand side, specialised from the general tree domain isomorphism.

`sexDomainEquationIso.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.SexRhs

@[expose] public section

namespace DomainTheory.BridgeTheorems
```

```
noncomputable def sexDomainEquationIso :
    SexSys.Element ≃o SexRhs.Element :=
  treeDomainIso lowerBoundSystem

end DomainTheory.BridgeTheorems
```

6.10.7 The semantic factor of the separated sum

Definition (`sexRhsSemanticIso`). The order isomorphism identifying the right-hand side with the lifted disjoint union of the tree domain and the product of the tree domain with itself.

`sexRhsSemanticIso.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.SexRhs

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems.InfoSys

noncomputable def sexRhsSemanticIso :
    WithBot (lowerBoundSystem.Element ? (SexSys.Element × SexSys.Element)) ≃o
      SexRhs.Element :=
  let ιProd := InfoSysConstructions.productDomainIso SexSys SexSys
  let ιSum := InfoSysConstructions.sumDomainIso lowerBoundSystem (productSystem SexSys
    SexSys)
  let mid :=
    (OrderIso.refl lowerBoundSystem.Element).sumCongr ιProd |>.withBotCongr
  mid.trans ιSum

end DomainTheory.BridgeTheorems
```

6.10.8 Neighbourhood filters, ideals, and the identity on the tree domain

Definition (`sexNeighborhoodIso`). Elements of the tree system are order-isomorphic to filters of its basic-open neighbourhood system.

Definition (`sexIdealIso`). Elements of the tree system are order-isomorphic to ideals of its finite elements.

Definition (`sexNeighborhoodIdealIso`). Filters of the basic-open neighbourhood system are order-isomorphic to ideals of finite elements, by composing the two previous isomorphisms.

Definition (`sex_bridge_1982_1980`). Alias for `sexNeighborhoodIso`, the SExpr landing 1982 ≃o 1980.

Definition (`sex_bridge_1982_1972`). Alias for `sexIdealIso`, the SExpr landing 1982 ≃o the 1972 algebraic carrier.

Definition (`sexIdScottContinuous`). The identity function on tree elements, packaged as a Scott-continuous map.

Basic.lean

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.sexAtom
public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.sexRhsSemanticIso
public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.sexDomainEquationIso

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems.InfoSys
open Order

noncomputable abbrev sexNeighborhoodIso :
    SexSys.Element ≃o (InfoSysToNeighborhood.toNeighborhoodSystem SexSys).Element :=
  InfoSysToNeighborhood.domainOrderIso SexSys

noncomputable abbrev sexIdealIso :
    SexSys.Element ≃o Ideal (InfoSysToIdealCompletion.FiniteElement SexSys) :=
  InfoSysToIdealCompletion.domainOrderIso SexSys

noncomputable abbrev sexNeighborhoodIdealIso :=
  neighborhood_ideal_iso SexSys

/-- SExpr landing: 1982 ≃o 1980. -/
noncomputable abbrev sex_bridge_1982_1980 := sexNeighborhoodIso

/-- SExpr landing: 1982 ≃o 1972 algebraic carrier. -/
noncomputable abbrev sex_bridge_1982_1972 := sexIdealIso

noncomputable abbrev sexIdScottContinuous : ScottContinuous SexSys SexSys :=
  (approximableMap_scottContinuous_equiv SexSys SexSys) (idMap SexSys)
end DomainTheory.BridgeTheorems
```

6.10.9 The right-hand side is a separated sum of a product

Theorem (`sexRhs_eq_sum_product`). The right-hand side information system is definitionally the separated sum of the product of the tree system with itself.

Proof. Specialise the general identity for tree right-hand sides. ■

sexRhs_eq_sum_product.lean

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems.InfoSys

theorem sexRhs_eq_sum_product :
```

```
    SexRhs = sumSystem lowerBoundSystem (productSystem SexSys SexSys) :=
  treeRhs.eq_sum_product lowerBoundSystem

end DomainTheory.BridgeTheorems
```

6.10.10 An atom belongs to its singleton closure

Theorem (`sexAtom_mem_self`). A natural-number atom belongs to the carrier of its singleton closure.

Proof. Closure contains the generating consistent set. ■

`sexAtom_mem_self.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems.InfoSys
open treeSystem

theorem sexAtom_mem_self (n : ℕ) : TreeToken.atom n ∈ (sexAtom n).carrier :=
  closure.subset SexSys (SexSys.con_sing _) (Finset.mem_singleton_self _)

end DomainTheory.BridgeTheorems
```

6.10.11 Unfolding an atom into the left summand

Theorem (`sexUnfold_atom`). Unfolding a singleton atom along the tree equation lands in the left summand.

Proof. Atoms unfold to left injections of atoms. ■

`sexUnfold_atom.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems.InfoSys

theorem sexUnfold_atom (n : ℕ) :
    treeUnfold lowerBoundSystem (.atom n) = SumToken.left n :=
  treeUnfold.atom lowerBoundSystem n

end DomainTheory.BridgeTheorems
```

6.10.12 Unfolding along the tree equation

Theorem (`sexDomainEquationIso_unfold`). The forward map of the tree-equation isomorphism is unfolding of elements.

Proof. Unfold the definition of the specialised domain isomorphism. ■

`sexDomainEquationIso_unfold.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems.InfoSys

theorem sexDomainEquationIso_unfold (x : SexSys.Element) :
    (sexDomainEquationIso x).carrier =
      treeUnfold lowerBoundSystem '' x.carrier :=
  rfl

end DomainTheory.BridgeTheorems
```

6.10.13 Folding along the tree equation

Theorem (`sexDomainEquationIso_fold`). The inverse map of the tree-equation isomorphism is folding of elements.

Proof. Unfold the definition of the specialised domain isomorphism. ■

`sexDomainEquationIso_fold.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems.InfoSys

theorem sexDomainEquationIso_fold (y : SexRhs.Element) :
    (sexDomainEquationIso.symm y).carrier =
      treeUnfold lowerBoundSystem ^-1' y.carrier :=
  rfl

end DomainTheory.BridgeTheorems
```

6.10.14 Existence of the tree-equation isomorphism

Theorem (`exists_sexDomainEquationIso`). There exists an order isomorphism between the tree domain and the right-hand side of the tree equation.

Proof. The packaged tree-equation isomorphism supplies one. ■

`exists_sexDomainEquationIso.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

theorem exists_sexDomainEquationIso :
    Nonempty (SexSys.Element ≃o SexRhs.Element) :=
  ⟨sexDomainEquationIso⟩

end DomainTheory.BridgeTheorems
```

6.10.15 Existence of the neighbourhood-filter isomorphism

Theorem (`exists_sexNeighborhoodIso`). There exists an order isomorphism between tree elements and filters of basic opens.

Proof. The packaged neighbourhood isomorphism supplies one. ■

`exists_sexNeighborhoodIso.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

theorem exists_sexNeighborhoodIso :
    Nonempty (SexSys.Element ≃o
      (InfoSysToNeighborhood.toNeighborhoodSystem SexSys).Element) :=
  ⟨sexNeighborhoodIso⟩

end DomainTheory.BridgeTheorems
```

6.10.16 Existence of the ideal isomorphism

Theorem (`exists_sexIdealIso`). There exists an order isomorphism between tree elements and ideals of finite elements.

Proof. The packaged ideal isomorphism supplies one. ■

`exists_sexIdealIso.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

open Order

theorem exists_sexIdealIso :
    Nonempty (SexSys.Element ≃o
      Ideal (InfoSysToIdealCompletion.FiniteElement SexSys)) :=
  ⟨sexIdealIso⟩

end DomainTheory.BridgeTheorems
```

6.10.17 The identity map on tree elements

Theorem (`sexId_toElement`). The underlying function of the identity Scott-continuous map is the identity on tree elements.

Proof. Unfold the packaging of the identity map. ■

`sexId_toElement.lean`

```
module

public import DomainTheory.BridgeTheorems.WorkedExampleSExpr.Basic

@[expose] public section

namespace DomainTheory.BridgeTheorems

open DomainTheory.InformationSystems.InfoSys

theorem sexId_toElement (x : SexSys.Element) :
    sexIdScottContinuous.toFun x = x :=
  idMap.toElement SexSys x

end DomainTheory.BridgeTheorems
```

7 Acknowledgments

7.1 AI-assisted development

The human author retains sole responsibility for the mathematical content, the choice of formalization route, and every formal claim in this work. Following standard publisher practice (e.g., COPE guidance on authorship and AI tools [5]), **no large language model is listed as a co-author** — authorship implies an accountability that automated systems cannot bear.

We gratefully acknowledge assistance from the following tools in this revision (auto-generated from `scripts/ai_model_cards.py` when building `arxiv.tex`). Source versions of the four Scott papers and the bridge theorems record their own model cards in their respective writeups under `vendor/`:

- **Cursor Composer 2.5** [6] — routine multi-step work: module scaffolding, dependency-ordered wiring of `DomainTheory/`, documentation and Mermaid blueprints, and medium proof obligations where the strategy was already fixed (`composer-2.5`).
- **Cursor Grok 4.7** [7] — primary agent model for the DomainTheory sessions: domain-theory constructions, inventory design in `arxiv.md`, constructivity audits, and adaptation of portable patterns from prior Scott formalizations. Used here via the Cursor agent environment.
- **Google Gemini 3.8** [8] — exploratory and support passes (typographic conventions, scope decisions, and cross-checks against the narrative inventory).

All definitions, constructivity audits, and final prose were reviewed by the human author, who takes full responsibility for them.

7.2 Artifact availability and reproducibility

The development is at `github.com/catskillsresearch/DomainTheory`. GitHub Actions CI runs `lake build` on `main`.

Locally:

```
lake exe cache get
lake build DomainTheory
```

Sibling packages `scott1972`, `scott1976`, `scott1980`, `scott1982`, and `scott_models` are vendored under `vendor/` (frozen revisions in `vendor/FROZEN.txt`); they are not Lake path dependencies. `arxiv.md` is the durable inventory and proof narrative. Axiom audits: `#print axioms` on the compared names in `comparator.json`.

Build the CMU-CS technical report PDF (Lean Code appendix = GitHub hyperlinks):

```
./aa.sh                              # DomainTheory.md → DomainTheory.pdf
# or: bash scripts/build_arxiv_pdf.sh
```
